## Abstract

The increasing demand for construction materials along with the challenge of waste management has necessitated the development of sustainable materials utilising wastes properly. Therefore, this research examines the utilisation of various agricultural wastes, such as Eggshell Powder (ESP), Sawdust Powder (SDP) and Coconut Husk Powder (CHP), in the production of unfired clay blocks. Samples were made with various percentages of wastes: 10-50% of dry wt. of clay for ESP and 2.5-10% for SDP and CHP. In this study, the physico-mechanical and durability properties of unfired clay blocks were investigated by conducting density, linear shrinkage, capillary water absorption, flexural strength, compressive strength, ultrasonic pulse velocity test, drip test and water spray test. The tests were carried out in two phases, with the first phase including the individual integration of waste in the mixture and the second phase combining ESP (10-30%) with the optimum SDP (2.5%) and CHP (2.5%). The test results show that when the additives were used individually, the 40% ESP samples performed the best whereas for SDP and CHP 2.5% content showed better performance. Contrarily, the samples' overall characteristics deteriorated when ESP, SDP, and CHP were used together. Nevertheless, all of the samples met the strength requirement of the standards and passed the durability tests. The results of this study might be useful in assessing the potential of ESP, SDP and CHP for the production of unfired clay blocks as well as finding a solution to the waste management problem.

**Keywords:** Agro-wastes, Durability properties, Mechanical properties, Physical properties, Unfired clay blocks.

## 1. Introduction

Currently, a new awareness of the application of sustainable and healthy materials in the construction sector is emerging in both developing and developed countries. The manufacturing processes of conventional building materials like concrete and fired earth bricks are not only expensive but also has negative environmental effects such as excessive energy demand and greenhouse gas emissions [1-3]. On the other hand, unfired earthen materials require approximately 99% less energy for the manufacturing process compared to concrete [4] and have less embodied energy (0.45 MJ/kg) than fired earth bricks (3 MJ/kg) [5]. There are also many other benefits for unfired earthen building materials, including regionally available raw materials, easy-to-construct, cost-effective, good hygrothermal properties and ease of recycling with minimum environmental effects [6-8]. Hence, unfired earthen materials are gaining growing attention as natural sustainable materials for building construction. However, there are some disadvantages associated with earthen structures such as poor mechanical and durability properties as well as regular repair [9-12]. Consequently, researchers have experimented with different additives and stabilisation techniques to enhance its properties and a substantial number of studies on this issue have been published in recent decades [13-15]. These investigations indicate that different stabilisers impart strength and durability to earthen materials to different extents depending upon the chemical compositions and physico-mechanical properties of individual stabiliser. Researchers have

suggested many kinds of man-made stabilisers such as cement, lime, plastic waste, synthetic fibre etc. to improve the performance of the earthen materials [16-20]. Cement, though, is a source of CO<sub>2</sub> emissions from these stabilisers, is the most commonly used one [21-23]. The use of man-made stabilisers, on the other hand, lowers the “green” aspects of earthen materials by increasing embodied energy levels and reducing the recycling potential of demolished wastes. To overcome this, the utilisation of natural materials such as agricultural residues for earth stabilisation is becoming widespread among researchers [24-28].

The global development of the agricultural industry produces large volumes of agro-wastes annually and a growing environmental concern has emerged from the accumulation of unmanaged residues particularly in developing countries. In recent years, scientists have tried to reduce the amount of agro-wastes by finding new applications. Since alternative material studies now explicitly prioritise the reduction of energy usage and the resolution of waste management problems, several studies have shown that this challenge can be achieved by using agro-wastes for building material production [14, 29, 30]. Studies reveal that utilisation of the agro-wastes as stabilisers in the production of unfired earthen materials is more beneficial than man-made materials in terms of environmental (energy-saving), economic (cost-reducing) and ecological (resource-saving) perspectives [31]. It is more economical to use regionally available vernacular agro-wastes as they require less processing and negligible transportation cost [32]. Depending on the availability, various agro-wastes have already been

1 utilised to improve the characteristics of unfired clay  
2 bricks in different countries. According to several  
3 studies [14, 29, 30], the inclusion of agro-wastes into the  
4 unfired clay bricks has often resulted in improved  
5 characteristics. Therefore, this present study aims at  
6 utilising three agro-wastes namely eggshell, sawdust  
7 and coconut husk to evaluate their possible application  
8 as the alternative raw materials to enhance the  
9 performance of developed unfired clay blocks.  
10 Moreover, utilisation of these agro-wastes in the  
11 production of sustainable construction materials  
12 contributes to a feasible solution to the waste  
13 management problem.

14 Eggshells are considered waste materials  
15 mainly generated by the poultry and food industries. The  
16 total global production of eggshells is around 110 billion  
17 tonnes which eventually ends up going to landfill sites  
18 [33]. It is observed that eggshells are high in calcium  
19 levels ranging from 94% to 98% [34-36]. Also, calcium  
20 in eggshells is more absorbable than the calcium  
21 contained in limestone or coral sources [37] which  
22 contributes to reinforcing material bonding [38] and this  
23 feature of the poultry eggshells has made it an attractive  
24 choice for natural reinforcement. Hence, scientists have  
25 started investigations to use eggshells for developing  
26 different types of valuable and utilisable products [33,  
27 37, 39-42]. Several recent studies showed that eggshell  
28 powder and eggshell ash can be used for soil  
29 stabilisation [43-47] and making building materials such  
30 as unfired laterite brick [38, 48], fired brick [49, 50],  
31 sandcrete block [51], concrete block [52, 53] and soil  
32 cement brick [54]. Ayodele et al. [48] developed  
33 lateralised unfired bricks incorporating combinations of  
34 sawdust ash and eggshell ash of 0-16 wt.%. The test  
35 results revealed that the density of the samples increased  
36 steadily up to 4% ash content, after which it started to  
37 decrease for higher ash percentage and the maximum  
38 compressive strength was achieved for 2-4% ash  
39 content. In another study, Adogla et al. [38] assessed the  
40 potentiality of eggshell powder (0-40 wt.%) in the  
41 production of unfired compressed bricks. It was  
42 observed that incorporation of eggshell increased the dry  
43 density of the samples and the samples with 30%  
44 eggshell showed better performance in compressive  
45 strength, water absorption and abrasion resistance test.

46 On the other hand, sawdust or wood dust is the  
47 fine wood particle produced as a by-product of the wood  
48 or timber industry. Generally, sawdust has wood-like  
49 characteristics although certain structural properties  
50 have been modified due to its particle nature. The  
51 chemical composition of dry wood varies by species of  
52 trees. The main chemical components in sawdust are  
53 lignin (18-35%) and carbohydrate (65-75%) while small  
54 quantities of extraneous materials (4-10%) are also  
55 found [55, 56]. The bulk density of sawdust is found to  
56 be very low (150-200 kg/m<sup>3</sup>) [57] and it has a very low  
57 thermal conductivity, making it suitable for insulation  
58 material [58, 59]. Researchers conducted experiments  
59 using sawdust for manufacturing different types of  
60 building materials [60]. Some of the developed

61 materials include particleboard [61-65], insulation  
62 material [66], cement concrete brick [67, 68], fired clay  
63 brick [58, 69-73] and unfired brick [24, 48, 74-80].  
64 Demir [74] examined the compressive strength of  
65 unfired clay bricks containing 2.5 to 10% sawdust and  
66 found that adding sawdust to unfired bricks enhanced  
67 compressive strength. Similarly, Ouattara et al. [76]  
68 observed an improvement in the compressive strength of  
69 clay bricks with 15-20% of sawdust content. However,  
70 the study of Ganga et al. [75] showed no improvement  
71 in compressive strength of the samples with the addition  
72 of sawdust or mahogany shavings. In another study,  
73 Vilane [24] produced adobe bricks with sawdust (0-  
74 20%) and obtained the optimum percentage to be 15%  
75 as it gave the highest compressive strength. Jokhio et al.  
76 [79] found higher compressive strength values by  
77 replacing sand with 20% sawdust, while the study  
78 observed a decreasing trend in flexural strength. The  
79 water absorption properties of sawdust lignin and  
80 cement (4, 8 and 12% by mass) stabilised compressed  
81 earth blocks were assessed by Fadele and Ata [77] and  
82 the results indicated better performances of sawdust  
83 stabilised samples than the cement stabilised samples.  
84 According to Charai et al. [78], the density and thermal  
85 conductivity of the sawdust clay composites decreased  
86 with the increasing amount of sawdust from 2-10 wt.%.  
87 De Castrillo et al. [80] used straw and sawdust (30%-  
88 70% by volume) to produce traditional adobe bricks.  
89 According to the finding, the bulk density, thermal  
90 conductivity, flexural and compressive strength of the  
91 adobes all reduced as the proportion of both fibres in the  
92 samples increased. Moreover, sawdust adobes showed a  
93 gradual rise in capillary water absorption than the straw  
94 adobes with the increase in fibre percentage.

95 Coconut husk is another agricultural waste that  
96 is the by-product of coconut production mainly obtained  
97 from the outer shell. Coconut is a tropical plant that  
98 grows largely at latitudes between 20°N and 20°S [81].  
99 Although billions of coconuts are produced each year,  
100 only 15% of the residual fibres from the harvesting  
101 process are used as materials for manufacturing  
102 purposes [82]. The coconut husk contains  
103 approximately 75% of coconut coir fibres and 25% of  
104 the pith [83, 84]. The coconut coir is reddish-brown and  
105 composed of cellulose, hemicellulose, lignin and pectin  
106 [85]. Studies show that the addition of coconut coir can  
107 reduce the thermal conductivity of the composite and  
108 result in a lightweight product due to its low bulk density  
109 [86, 87]. Coconut coir has been examined by many  
110 researchers in manufacturing different construction  
111 materials such as insulation board [88], fibreboard [89],  
112 particleboard [90], concrete block [91-94], fired brick  
113 [95-97] and unfired earth block [98-102]. Besides, it has  
114 been used for soft soil stabilisation [103-105]. Khedari  
115 et al. [90] [99] assessed the thermal properties of unfired  
116 soil blocks using coconut coir fibre (10-20% of  
117 reference cement volume) and the findings showed that  
118 the presence of coconut fibres reduced the density,  
119 thermal conductivity and compressive strength of the  
120 sample blocks. The study recommended a 20% ratio as

the optimum for the best thermal performance. Danso et al. [98] produced unfired clay blocks using various proportions (0.25-1 wt.%) and lengths (38 mm, 50 mm and 80 mm) of coconut fibre. The findings showed that dry density reduced but water absorption increased with the addition of fibre. Also, both compressive and tensile strength improved significantly by adding fibre up to 0.5%. In the study of Thanushan et al. [100] incorporation of coconut fibre from 0.2-0.6% of mass portions caused a gradual decrease in compressive and flexural strength but an increase in water absorption values. Sangma et al. [101] studied the physico-mechanical properties of unfired earth blocks by adding 5% and 20 mm to 80 mm coir fibre. The study concluded that the reinforced blocks had higher tensile and compressive strength than the unreinforced blocks and the 40 mm long coconut fibre performed the best. Purnomo and Arini [102] performed experiments on coconut coir (treated) reinforced unfired bricks to investigate how humidity influences its physico-mechanical properties. The results revealed that in wet conditions the brick samples with 4% treated and 25 mm coir fibre exhibited better mechanical properties than the other samples.

From the literature, it can be noticed that research on the effect of eggshell, sawdust and coconut husk on selected properties of unfired clay blocks is limited. Hence, this study presents the physico-mechanical and durability properties of the developed

unfired clay blocks utilising eggshell, sawdust and coconut husk. The experimental study was conducted in two series. In the first series of the tests, various percentages of eggshell, sawdust and coconut husk were added in the mixture individually to produce the samples and their properties were examined. Based on the results from the first series, a second series was performed to assess their combined effect. The results of both series of experimental tests were analysed and discussed.

## 2. Raw materials and sample preparation

### 2.1. Materials

The substances employed in the production of unfired clay samples are Red Clay Powder (RCP), Eggshell Powder (ESP), Sawdust Powder (SDP), Coconut Husk Powder (CHP) and water (Fig. 1). The clay used in this study was supplied by Bath Potters' Supplies, UK. It is a raw reddish powdered clay that is dug directly from the ground and contains some pebbles since it is in its natural state. The ESP, SDP and CHP used were obtained from the local retailers in the UK. The raw materials were sieved with the square mesh sieve to have a controlled particle size between 212  $\mu\text{m}$ -150  $\mu\text{m}$  for ESP and 600  $\mu\text{m}$ -425  $\mu\text{m}$  for SDP and 1.18 mm-300  $\mu\text{m}$  for CHP. In the mixtures, normal tap water was used.

Fig. 1. Raw materials: (a) RCP, (b) ESP, (c) SDP and (d) CHP.

### 2.2. Characterisation of raw materials

Standard proctor compaction test [106] was used to experimentally determine the optimum moisture content and maximum dry density while BS 1377-2:1990 standard [107] establishes the Atterberg limit of clay. Chemical properties and mineralogical phase evolution of RCP, ESP, SDP and CHP were assessed by means of X-ray Fluorescence (XRF) (EDX-720 Shimadzu, Japan) and X-ray Diffraction (XRD) (Rigaku MiniFlex) analysis respectively. Moreover, in this study, the surface morphology of raw materials was characterised by Scanning Electron Microscope using an FEI Inspect S SEM model at 20 kV accelerating voltage after gold-coating the materials. Besides, the density was determined by the cylinder method and porosity was measured following the method of

Horisawa et al. [108]. Furthermore, specific gravity was obtained according to the BS EN 1097-6 standard [109].

The physical and chemical properties of the raw materials are summarised in Table 1 and Table 2 respectively. The proctor compaction test on clay revealed a maximum density of 2320  $\text{kg/m}^3$  at an optimum moisture content of 15.50%. Furthermore, the clay had a plastic limit of 19.25% water content and a liquid limit of 31.61%, indicating that it was a medium plastic clay with a plasticity index of 12.36%. Fig. 2 shows the grain size distribution curve of the RCP determined by sieve analysis [110]. The bulk densities of RCP, ESP, SDP and CHP were measured as 1.43  $\text{g/cm}^3$ , 1.17  $\text{g/cm}^3$ , 0.23  $\text{g/cm}^3$  and 0.13  $\text{g/cm}^3$  with specific gravities of 2.32, 1.74, 1.14 and 0.61 respectively. Besides, CHP was more porous in nature (7.65) compared to SDP (5.09) and ESP (0.56) and

according to the water absorption test, CHP had a higher absorption rate (195.16%) than SDP (127.66%) and ESP (39.42%).

The XRD analysis (Fig. 3(a)) displays the presence of quartz ( $\text{SiO}_2$ ), kaolinite ( $\text{Al}_2(\text{Si}_2\text{O}_5)(\text{OH})_4$ ) and haematite ( $\text{Fe}_2\text{O}_3$ ) in RCP. This is also supported by the XRF test findings shown in Table 2. Silica and aluminium were found in the clay, making it a pozzolan. Furthermore, the presence of ferric oxide ( $\text{Fe}_2\text{O}_3$ ) highlights the redness of clay. On the other hand, ESP was found as a non-pozzolan material since it lacked siliceous and aluminous elements. However, ESP had a significant quantity of calcium oxide ( $\text{CaO}$ ) obtained from the calcination of calcite ( $\text{CaCO}_3$ ), which is

necessary for a pozzolanic reaction to affect the cementitious characteristics of clay bricks (Fig. 3(b)) [111]. Also, the disordered XRD patterns indicate the presence of amorphous phases (hemicelluloses and lignin) in SDP and CHP (Fig. 3(c) and Fig. 3(d)).

The SEM images of the raw materials are illustrated in Fig 4. It can be observed that eggshells had agglomerated irregular stone-like shape particles (Fig. 4(b)). On the other hand, sawdust particles came in a variety of sizes and forms, with rough surfaces including heterogeneous fibres with multiple protrusions and folds (Fig. 4(c)). Fig. 4(d) shows that coconut husk particles had an irregular honeycomb-like spongy structure consisting of many pores.

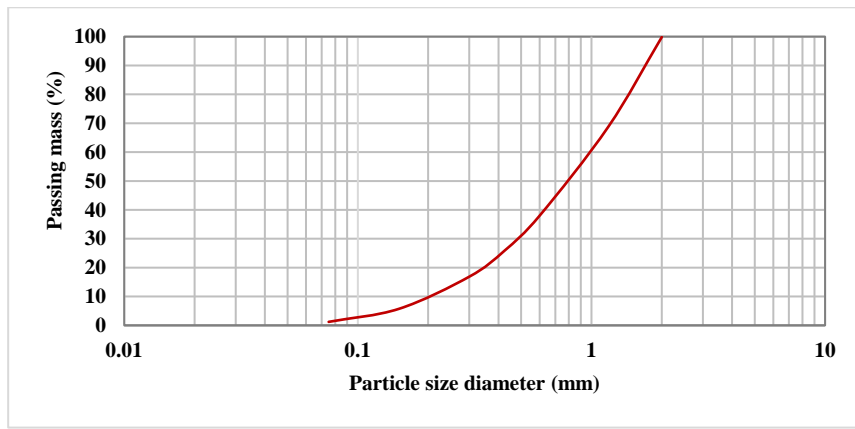

Fig. 2. Particle size distribution curve of RCP.

Fig. 4. SEM images: (a) RCP, (b) ESP, (c) SDP and (d) CHP.

2.3. Sample preparation

The experiment programme was conducted in two phases. In the first phase clay samples with five different percentages of ESP (10%, 20%, 30%, 40% and 50% by weight of clay) and four percentages of SDP and CHP (2.5%, 5%, 7.5% and 10% by weight of clay) were

produced. According to the findings of the first phase, in the second phase, ESP was combined with optimum SDP and CHP to make the sample blocks. Table 3 gives the mixing proportions of the experiment of the first phase. Samples for the physical and mechanical properties tests were prepared in prismatic moulds of 40 mm × 40 mm × 160 mm (Fig. 5(a)) following the British

standard BS-EN 1015-11 [112] for cement mortars which are frequently used for unfired brick studies due to the lack of the specific standards. Three samples were tested for each percentage and the tests included density, linear shrinkage capillary water absorption, flexural and compressive strength. On the other hand, for durability tests samples of 100 mm × 100 mm × 100 mm and 65 mm × 102 mm × 215 mm were cast (Fig. 5(b) and Fig. 5(c)). First clay was passed through a sieve with a 2.00 mm<sup>2</sup> mesh size to remove any lumps. Then dry clay and waste materials were thoroughly mixed in a mechanical mixer machine. Afterwards, based on the proctor test 15.50% of water by dry weight of clay was gradually added to the dry mixture to obtain the optimum moisture content and homogeneity for moulding the samples. To maintain the same consistency for moulding quantity of water in each series was adjusted. The mixture was put into the moulds in two layers and each layer was manually compacted with 25 blows. Uniform

compaction may not have been accomplished in this investigation due to the hand compaction. However, hand compaction was applied to interpret the production of unfired clay brick in rural areas where advanced apparatus is unavailable. The samples were covered with plastic bags for 24 hours after being moulded to ensure uniform water absorption and no sudden loss of moisture. Before demoulding, the samples were then dried at the laboratory room temperature of around 23-26°C and relative humidity of 30-34% for 7 days. Clay samples were dried naturally to slowly dissipate the moisture and reduce internal crack due to shrinkage. After demoulding, the samples were dried for another 21 days in the same laboratory conditions before being examined. Although the absence of cement in the blends implies that no curing period is needed by the standards, this drying period was chosen as most traditional unfired clay brick manufacturers use it.

**Table 3** Mix details (First phase).

| Sample ID | Clay (g) | Waste (%) |     |     | Waste (g) |       |       |
|-----------|----------|-----------|-----|-----|-----------|-------|-------|
|           |          | ESP       | SDP | CHP | ESP       | SDP   | CHP   |

### 3. Tests

Density, linear shrinkage, compressive strength, flexural strength, capillary water absorption, ultrasonic pulse velocity (UPV) test, drip test, and water spray tests were performed on the samples. A review study of prior research [22, 30] led to the selection of these tests, which included a wide range of physical, mechanical and durability properties relevant to unfired clay blocks. Moreover, XRD analysis was used to study the crystal structure of the clay composite. Samples dried for 28 days were grounded into fine powder to use for the analysis. Tests were performed on a Rigaku mini-

flex X-ray diffractometer using Cu K $\alpha$  radiation generated at 30kV and 15 mA. The samples were scanned in continuous scan mode at an angular speed of 2°/min and the measurements were taken for 2 $\theta$  angle from 5° to 60°.

#### 3.1. Density test

The density of materials has influences on their properties like strength, heat and conductivity. In this study, BS EN 771-1 [113] standard was followed to determine the densities of the samples. The test procedure can be described as follows: the 28-day dry

1 samples (average of three samples per mix composition)  
 2 were carefully cleaned with a cloth to eliminate any  
 3 loose substance attached. Then all dimensions of the  
 4 sample along the edge were measured using a digital  
 5 calliper (precision 0.01 mm) and the average value for  
 6 each dimension was calculated. The volume ( $V$ , m<sup>3</sup>) and  
 7 mass ( $M$ , kg) of the samples were measured and the  
 8 density ( $\rho$ , kg/m<sup>3</sup>) was determined using the following  
 9 Eq. (1):

$$\rho = \frac{M}{V} \quad (1)$$

### 10 3.2. Linear shrinkage test

11 Shrinkage control is crucial for preventing the  
 12 deformation and cracking of the samples. It is a physical  
 13 phenomenon that is caused by the evaporation of  
 14 moisture content in the samples during the drying  
 15 process. The linear shrinkage test was performed  
 16 following the BS EN 772-14 [114] standard on three  
 17 samples per mix composition. For the test procedure,  
 18 four dimensions of the prism mould length ( $L_i$ , mm)  
 19 were measured and at the end of the 28-day drying  
 20 period, the four dimensions of the prism sample length  
 21 ( $L_d$ , mm) were recorded using a digital calliper. The  
 22 average length was then taken and Eq. (2) was used to  
 23 calculate the linear shrinkage ( $S_d$ , %):

$$S_d = \frac{L_i - L_d}{L_i} \times 100 \quad (2)$$

### 25 3.3. Flexural strength test

26 A 25 kN frame capacity Tinius Olsen H25KS  
 27 was used to test the flexural strength under three-point  
 28 loading in accordance with BS EN 1015-11 [112]. The  
 29 test was performed on the full prism samples (40 mm ×  
 30 40 mm × 160 mm) after 28 days of the drying period.  
 31 The clear span between the two supports was 100 mm  
 32 as shown in Fig. 6 and the load was applied at a rate of  
 33 10 N/s at the middle of the samples until it failed. Three  
 34 samples from each mix design were tested resulting in  
 35 the formation of half samples at the end of the test which  
 36 were then used for compressive strength and capillary  
 37 water absorption tests. The following Eq. (3) from EN  
 38 1015-11 was used to determine the flexural strength:

$$f = \frac{1.5FL}{bd^2} \quad (3)$$

39 Where  $f$  (MPa) is the flexural strength,  $F$  (N) is the  
 40 obtained load,  $L$  (mm) is the distance between the  
 41 supports,  $b$  (mm) is the height of the sample, and  $d$  (mm)  
 42 is the width of the sample.

Fig. 6. Flexural strength test: (a) schematic and (b) experimental.

### 45 3.4. Compressive strength test

46 Half prism samples with an average dimension  
 47 of 40 mm × 40 mm × 80 mm were tested for  
 48 compressive strength according to the BS EN 1015-11  
 49 [112] standard. Three samples were examined and mean  
 50 values were calculated for each mix design. A  
 51 computerised and motorised triaxial machine was used  
 52 for the test (Fig. 7). According to the standard, the  
 53 samples were aligned centrally between two bearing  
 54 steel plates of 40 mm × 40 mm and the charge velocity

55 used was 0.40 MPa/s until visible damage was caused  
 56 by the compression. The compressive strength was  
 57 determined using the Eq. (4):

$$C = \frac{F}{A} \quad (4)$$

58 Where  $C$  (MPa) is the compressive strength,  $F$  (kN) is  
 59 the ultimate load,  $A$  (mm<sup>2</sup>) is the area of the bed face.

Fig. 7. Compressive strength test: (a) schematic and (b) experimental.

### 3.5. Capillary water absorption test

The capillary water absorption test was performed to determine the ability of the waste-incorporated clay samples to resist the absorption and retention of water. BS EN 1015-18 [115] specifies the test method on one half prism sample (40 mm × 40 mm × 80 mm) obtained from the flexural strength test. Following the standard, to attain constant mass the half prisms were first dried for 24 hours at  $60 \pm 5$  °C in a ventilated oven and the mass of the oven-dried samples were recorded. As the samples had dissimilar sizes after the breakage in the flexural strength test, flat faces of the

samples were immersed in a constant head-water bath to a depth of 5 mm for 10 min to ensure consistency (Fig. 8). Then after 10 min, the samples were removed from the water and their mass were noted. The capillary water absorption was calculated (average of three samples per mix composition) by the following Eq. (5) [115]:

$$C_w = 0.1 \times (M_t - M_i) \quad (5)$$

Where  $C_w$  ( $\text{kg}/(\text{m}^2 \times \text{min}^{0.5})$ ) is the capillary water absorption coefficient,  $M_i$  (g) is the initial mass of the sample and  $M_t$  (g) is the mass of the sample after 10 min.

Fig. 8. Capillary water absorption test: (a) schematic and (b) experimental.

### 3.6. UPV test

Low density and high absorption potential agro-wastes can affect the porosity and consequently, the strength of the samples. Hence, the UPV test which is a non-destructive procedure for assessing the presence of voids and density of samples. The test was performed on the 65 mm × 102 mm × 215 mm samples after 28 days of casting using a Proceq Pundit PL-200 ultrasonic pulse equipment. This equipment measures the delay time required for a transmitted ultrasonic wave to travel from the transducer and return to the transducer through the interposed sample. A coupling gel was applied between

the samples and transducers to avoid the existence of voids in the contact area. The samples were measured for length (L), width (W) and height (H) prior to the test in order to determine UPV for each direction (Fig. 9(a)). The direct transmission (Fig. 9(b)) was used to measure the UPV as it is considered the most reliable configuration [116]. The test findings can be used in determining the durability of the samples by assessing the decrease of voids inside the samples as velocity increases with the decrease of voids suggesting a compact and denser composition.

Fig. 9. UPV test: (a) schematic and (b) experimental.

### 3.7. Geelong drip test

The wet erosion test was performed following the New-Zealand Standard NZS 4298 [117] which is based on the Geelong drip test method. This test method was originally developed at Deakin University, Australia to evaluate the capacity of the earthen materials to withstand erosion caused by light and indirect rainfall. Later Frencham [118] categorised the earthen materials by relating the depth of pitting to an Erodability index (Table 4) which relates the erosion to real-life performance [119]. The test was carried out on the 100 mm × 100 mm × 100 mm samples by simulating rain droplets. According to the procedure, the samples were positioned at a 30° angle at the base and vertically 400 mm away from a water container, from which water was allowed to drop on the surface of the samples at a controlled flow for 60 min (Fig. 10). After testing, the erodibility index was calculated by measuring the pit depth created by the water drops on the samples with a calliper of 0.01 mm resolution. This simple test can be acceptable in areas where annual precipitation is around 500 mm but its applicability in areas with higher rainfall levels has yet to be determined [119].

### 3.8. Water spray test (Pressure spray method)

The pressure spray test is also known as the ‘accelerated erosion test’ and is frequently used in practice. However, according to Heathcote [120] and Walker et al. [121], this test is more extreme than real climatic conditions. The test was carried out in accordance with New Zealand Standard NZS 4298 [117] to assess the resistance of the samples against continuous rainfall conditions. The test simulates two real-life conditions that cause earthen materials to erode due to moderate to heavy rainfall: humidification and kinetic energy. Humidification reduces the internal cohesion between the material particles by increasing

moisture content while kinetic energy is responsible for breaking the already weakened bonds of material particles. The test was performed on 65 mm × 102 mm × 215 mm samples imitating real-life conditions of average to heavy rainfall. The samples were placed behind a shield board and the external surface was exposed to a pressure spray through an 80 mm diameter hole (adapted from the standard from 100 mm diameter hole) on the shield board (Fig. 11). The pressure spray was positioned at 470 mm from the shield and tap water was sprayed through the nozzle at a pressure of 50 kPa onto the samples for an hour or until failure occurred. In every 15 min, the depth of pitting was measured using a calliper and the rate of erosion in mm per hour was determined by dividing the total depth of erosion by 60. In addition, samples were inspected by the eye to assess the degree of moisture penetration. The erodability index for the water spray test is specified in Table 5.

Table 4 Scale of assessment for ‘Drip test’.

| Depth of erosion, d (mm) | Frencham [118] recommendation | Erodability index as per NZS 4298 [117] |
|--------------------------|-------------------------------|---|
| 0                        | Non-erosive                   | 1                                       |
| $0 \leq d < 5$           | Slightly erosive              | 2                                       |
| $5 \leq d < 10$          | Erosive                       | 3                                       |
| $10 \leq d < 15$         | Very erosive                  | 4                                       |
| $15 \leq d$              | -                             | 5 (Fail)                                |

Table 5 Erodability indices from pressure spray erosion test.

| Erosion rate, d (mm/hr) | Erodability index |
|-------------------------|-------------------|
| 0                       | -                 |
| $0 \leq d < 20$         | 1                 |
| $20 \leq d < 50$        | 2                 |
| $50 \leq d < 90$        | 3                 |
| $90 \leq d < 120$       | 4                 |
| $120 \leq d$            | 5 (Fail)          |

## 4. Results and discussions

### 4.1. First phase

#### 4.1.1. Density

The effect of various ESP, SDP and CHP ratios on the density of the samples is shown in Fig. 12. It can be observed that densities of the samples decreased with

higher ESP, SDP and CHP content which were lower than that of the reference sample. This decrease in density is mainly attributed to the lower specific gravity of the ESP, SDP and CHP particles as compared to the RCP used in this study (see Table 1). The increased lighter wastes content displaced heavier clay content, resulting in a drop in sample density. The decrease in density for increasing ESP content from 10% to 50% in

the mixture corresponds to a decrease of about 5.51% to 14.34% and for 2.5% to 10% addition of SDP and CHP the decrease was about 12.14% to 29.39% and 17.48% to 33.94% respectively in comparison to the reference clay sample. Besides, both reference and ESP incorporated samples achieved density values that exceeded the minimum value of 1750 kg/m<sup>3</sup> stipulated in Indian Standard: IS 1725 [122] and Sri Lankan Standard: SLS 1382 [123]. However, in the case of SDP and CHP addition, only samples with 2.5% content met the standard requirement. Other manufactured samples can be categorised as lightweight clay brick as a

construction material by the standards [124]. Several authors noticed similar results with natural fibre addition in unfired clay blocks, where density dropped with increasing the amount of fibres [74, 78, 98-100, 124]. However, the results from this study was contrary to the findings of Amaral et al. [54] and Adogla et al. [38] which established that the density of the compressed laterite brick and soil-cement brick increased steadily with increasing ESP content. This might be due to the mechanical compaction technique used in block manufacturing [125, 126].

Fig. 12. Density results (First phase).

#### 4.1.2. Linear shrinkage

Shrinkage is highly affected by the nature and quantity of additives, as well as their surface characteristic. Furthermore, the moisture absorption behaviour, water loss and porosity of the samples all have an impact on shrinkage [127, 128]. The results (Fig. 13) showed that when the SDP concentration increased from 2.5 to 10%, the linear shrinkage of the samples reduced from 6.05 to 5.53% which was up to around 31% reduction compared to the reference sample (8.07%). The bonding capabilities of SDP can be related to the presence of fibres in earthen materials like straw since they contain similar components. Straw in the earthen matrix plays a basic role in preventing shrinkage and subsequent fissuring during the drying process particularly if the earth is produced in blocks with high clay content [24]. Bouhicha et al. [129], Murillo et al. [130] and Danso et al. [98] reported a similar result in which natural fibres addition in the soil decreased the shrinkage by resisting soil matrix deformation via friction and/or adhesion. On the contrary, the samples

with CHP tended to shrink gradually from 8.18 to 12.29% (around a 52% increase relative to reference sample) when the CHP content is increased from 2.5 to 10%. It may be due to the higher water absorption potential of CHP relative to SDP (see Table 1) which weakened the waste particle-clay bonding resulting in increased shrinkage during the drying period due to evaporation. Besides, CHP's ability to absorb water from capillary pores may cause volume reduction (contraction) and an increase in sample shrinkage (deformation). For ESP samples shrinkage gradually decreased from 6.92% to 5.61% with waste content varying from 10-50%. It might be related to the adsorption of calcium ions from ESP, which caused a rise in pore fluid viscosity [131-133]. It is stated that if the material shrinks more than 8%, the drying process can produce internal fractures and cracking [128]. Concerning this, the present study found shrinkage values in allowable ranges except for the reference and CHP samples.

Fig. 13. Linear shrinkage results (First phase).

1

### 2 4.1.3. Compressive and flexural strength

3 The results of the mechanical strength tests  
 4 have been summarised in Table 6. At each mixture, both  
 5 compressive and flexural strength were determined by  
 6 taking the average of the three results. The strength  
 7 enhancement in waste-incorporated clay mixture largely  
 8 depends on the development of waste particle-clay  
 9 matrix adhesion, clay matrix-clay matrix bonding and  
 10 waste particle-waste particle cohesion. These bonds can  
 11 be influenced by particle size, surface conditions and the  
 12 amount of waste present [134]. In this study,  
 13 compressive strength was performed for both air-dried  
 14 and oven-dried samples. After 28 days, both the  
 15 reference and waste-incorporated samples fulfilled the  
 16 minimum strength requirement of the standards (1 MPa-  
 17 2.80 MPa) [117, 123, 135, 136]. The results show that  
 18 compressive strength for the samples with ESP  
 19 increased gradually with an increase in waste content up  
 20 to 40% then the strength decreased for 50% ESP. This  
 21 result is also accompanied by the XRD analysis (Fig.  
 22 14(a)). Amaral et al. [54] and Adogla et al. [38] reported  
 23 comparable results where the highest compressive  
 24 strength was recorded at 30% ESP for soil-cement brick  
 25 and compressed earth block. The increase in strength  
 26 can be explained by the pozzolanic reaction of the clay  
 27 minerals with a high amount of calcium available in ESP  
 28 which formed a cementitious compound that dispersed  
 29 among the clay particles and improved the adhesion of  
 30 the clay matrix and ESP particles. As a pozzolan the clay  
 31 contains siliceous and aluminium elements, while ESP  
 32 is a non-pozzolan material [137, 138]. When clay, ESP  
 33 and water are mixed, a pozzolanic reaction occurs which  
 34 produce samples with cementitious properties. The  
 35 ESP's calcium oxide (CaO) reacts with water at first,  
 36 leading to the production of calcium hydroxide  
 37 (Ca(OH)<sub>2</sub>), also known as portlandite. Subsequently,  
 38 portlandite (Ca(OH)<sub>2</sub>) and silica (SiO<sub>2</sub>) or silicic acid  
 39 (Si(OH)<sub>4</sub>) are converted to form calcium silicate hydrate

40 (CaSiO<sub>3</sub>·2H<sub>2</sub>O) which has strong cementing properties  
 41 responsible for the strength of the materials [111].

42 The lower compressive strength associated with higher  
 43 ESP content may be due to the insufficient presence of  
 44 silica content in the clay matrix as a result of a higher  
 45 additive amount. Therefore, fewer pozzolanic reactions  
 46 occurred and unreacted portlandite was prevalent in the  
 47 mixture, resulting in a decrease in mechanical resistance  
 48 and an increase in porosity [139, 140]. On the other  
 49 hand, the XRD spectra revealed that when SDP and  
 50 CHP were mixed with clay no reaction occurred ((Fig.  
 51 14(b), Fig. 14(c)). It was observed that the addition of  
 52 SDP and CHP enhanced the compressive strength of the  
 53 samples in comparison to the reference sample,  
 54 nevertheless, the highest compressive strength was  
 55 obtained with the least amount of waste percentage  
 56 (2.5%). This increase in strength for 2.5% dosage is due  
 57 to the improved molecular cohesion since higher  
 58 cohesion leads to better compressive strength. For SDP  
 59 and CHP content of more than 2.5%, the strength value  
 60 decreased due to poor adhesion of the clay with the  
 61 waste particles. This loss in strength is also associated  
 62 with the increase in porosity caused by the inclusion of  
 63 lightweight SDP and CHP in the blend. The hydrophilic  
 64 characteristic of natural fibres might cause them to  
 65 absorb water and expand, efficiently pushing out on the  
 66 clay matrix throughout the mixing and drying stages of  
 67 sample production. Then at the end of the drying period,  
 68 the fibres lose their absorbed water and shrink back  
 69 nearly to their original dimensions forming very fine  
 70 voids around their periphery which weakens the  
 71 interfacial bond (Fig. 15) [141, 142]. Furthermore, SDP  
 72 and CHP were added to the mixture at the expense of

clay resulting in a reduction in silica content which led to producing more porous structures with lower compressive strength than silica composites without additives [124]. These findings are in line with the findings of Khedari et al. [99], Murillo et al. [130], Thanushan et al. [100] and Wang et al. [143]. The relatively lower compressive strength values of SDP samples compared to the CHP samples could be due to the roughness of the CHP particle surface which contributed to the good adhesion of the fibres to the clay matrix. ESP, SDP and CHP addition improved the compressive strength of the air-dried clay samples up to

39.90%, 16.75% and 17.73% and oven-dried samples up to 28.15%, 16.30% and 20.19% respectively compared to the reference sample.

Table 6 shows that flexural strength had similar trends of compressive strength values with increasing the SDP and CHP waste content. All the samples met the requirements of the standards (0.25 MPa-0.50 MPa) [117, 122, 136] of unfired earth blocks. The optimum values of flexural strength were recorded as 2.24 MPa at 40% ESP and 2.00 MPa at 2.5% SDP and 2.14 MPa at 2.5% CHP representing 47.37%, 31.58% and 40.79% increase over the reference sample (1.52 MPa).

**Table 6** Flexural and compressive strength test results of the stabilised clay blocks (First phase).

| Sample ID | Flexural strength (FS) |                    |                             | Air-dried Compressive strength (CS) |                    |                             | Oven-dried Compressive strength (CS) |                    |                             |
|-----------|------------------------|--------------------|-----------------------------|-------------------------------------|--------------------|-----------------------------|--------------------------------------|--------------------|-----------------------------|

#### 4.1.4. Capillary water absorption

The capillary water absorption test is usually used to determine the immersion resistance and durability in wet environments of clay bricks. The incorporation of additives to clay bricks results in the formation of porosity which increases capillary water absorption. The structure of pores and how they are interconnected determine the rate of capillary water absorption [134, 144, 145]. Samples with higher

coefficients absorb more water, showing higher porosity, whereas samples with lower coefficients absorb less water, indicating lower porosity. Fig. 16 presents a decreasing trend in capillary water absorption coefficient values with increasing ESP content from 0% to 40% before rising slightly at 50% ESP. This is consistent with the result of Amaral et al. [54] and Adogla et al. [38]. This decrease can be attributed to the pozzolanic reaction induced by the calcium ions in ESP, which increased bonding within the clay matrix while

1 reducing open porosity, similar to traditional lime [38].  
 2 However, the capillary water absorption coefficient  
 3 steadily amplified when SDP and CHP content  
 4 increased from 2.5 to 10% since beyond 2.5% additives  
 5 the bonding between the particles and the clay matrix  
 6 became weak resulting in the formation of  
 7 interconnecting voids which led to the increase in water  
 8 absorption kinetics. Moreover, the absorbent nature of  
 9 SDP and CHP may potentially play a role in the increase  
 10 in capillary water absorption [146]. This finding is in  
 11 accordance with previous research on lignocellulosic  
 12 fibre-earth composites which found that increasing  
 13 percentages of fibre resulted in higher absorption levels

14 [98, 100, 147, 148]. On the other hand, Villamizar et al.  
 15 [149] and Sharma et al. [150] found that increasing the  
 16 amount of natural fibres in compressed and adobe  
 17 blocks reduced the water absorption. In general, the  
 18 discrepancies in the impacts of all the additives studied  
 19 on capillary water absorption may be linked to their  
 20 stabilisation mechanism, type of bonding and  
 21 rearrangement pattern of particles which were  
 22 influenced by the nature of the additives, their particle  
 23 size and compaction method [77, 80, 149]. The addition  
 24 of ESP resulted in a 15% decrease in capillary water  
 25 absorption compared to the reference sample, whilst  
 26 SDP and CHP boosted it by 26 and 45%, respectively.

Fig. 16. Capillary water absorption results (First phase).

#### 4.1.5. UPV

The shape, size and number of pores affect the wave propagation speed, making it a good indicator of porosity and compactness. The greater the increase in porosity, the lower the ultrasonic speed. This implies that porosity and ultrasonic velocity are inversely related. UPV values for ESP, SDP and CHP mixed samples are shown in Fig. 17, ranging from 1263 m/s to 1453.33 m/s, 1560.33 m/s to 1318.33 m/s and 1384.67 m/s to 1123.00 m/s, respectively. Unfired earth blocks are rarely studied for UPV and there is only a few research that shows a link between UPV and compressive strength of earthen materials [128, 151-154]. In this study, the UPV results showed a similar trend as the compressive strength (Fig. 18). The

44 Maximum UPV values were obtained for samples  
 45 containing 40% ESP and 2.5% SDP and 2.5% CHP  
 46 which had the highest compressive strength. An increase  
 47 in UPV for the addition of ESP might be attributed to  
 48 the pozzolanic reactions of ESP, whereas a decrease in  
 49 UPV for increasing SDP and CHP content could be  
 50 related to increased porosity in the samples. The  
 51 variations in sample performance for different  
 52 orientations might be explained by a lack of  
 53 homogenisation of the clay mixture. The UPV findings  
 54 might give an intriguing supplementary data set that is  
 55 closely related to the mechanical strength results.  
 56 Consequently, this non-destructive method may be used  
 57 to qualitatively assess the quality of unfired earth blocks.

#### 4.1.6. Drip

The test was performed on cube samples of each mixture. The lower the depth, the better the sample's erosion resistance. Table 7 shows that all of the samples passed the drip test and the pitting depths were between 0 and 5 mm which means an erodibility index of 2 (see Table 4), indicating that they are "slightly erodible." The results demonstrate that ESP, SDP and CHP addition to clay improves its erosion resistance compared to the reference sample. The least erosive mixture with SDP and CHP was 2.5%, whereas the best performance with ESP was obtained with the mixture with 40% ESP. The good cohesion between waste particles and clay prevents water from penetrating the sample and clay particles from washing away by water which appears to be the explanation for the sample's good performance [155].

#### 4.1.7. Water spray

The results of the water spray test show the durability of the clay brick under severe rains. The erosion rates of clay samples containing different amounts of waste percentages are shown in Table 7. All of the samples exhibited erosion rates of less than 1 mm/hr, indicating that they could resist exposure to harsh weather conditions. Since a little investigation on

the impact of agro-wastes additives on the erosion resistance of earth bricks has been undertaken, it's difficult to generalise the findings, however, in this study, incorporating the ESP, SDP and CHP in the clay mixture considerably increased its resistance to water erosion when compared to the reference sample. Furthermore, when the results are compared it can be concluded that SDP brought better resistance than the other additives. It was also observed that the rate of erosion increased as the percentage of SDP and CHP increased in the sample. The poor interface between the waste particles and the clay was related to the reduced durability. But for ESP the erosion rate decreased gradually up to 40% of waste content and then increased for 50% ESP. This is related to the high filling capacity of the ESP in the clay matrix which resulted in firm bonding. Danso et al. [98] and Sharma et al. [150] showed that when the amount of natural fibre increased the durability of the soil matrix improved. According to the authors, this might be due to improved interaction between fibre and soil which binds soil particles together more firmly. Obonyo et al. [156], on the other hand, found that adding coir fibres in soil-cement blocks significantly reduced their durability against water. Also, Akinwumi et al. [157] observed that the durability of compressed earth block decreased with the increasing percentage of shredded waste plastic due to the poor interaction of the shredded waste plastic with the soil.

**Table 7** Drip test and water spray test results of stabilised clay blocks.

| Sample ID | Drip test            |                   |                  | Water spray test      |                         |                   |
|-----------|----------------------|-------------------|------------------|-----------------------|-------------------------|-------------------|

#### 4.2. Second phase

Results of the first phase indicate that the addition of 10-40% of ESP improved the strength and 2.5% SDP and CHP performed the best. Hence, in the second phase, 2.5% of SDP and CHP were combined with 10-30% of ESP to examine the properties of the clay samples (Table 8). It can be seen that when ESP was combined with SDP and CHP, the density (Fig. 19) and linear shrinkage reduced (Fig. 20) but capillary water absorption increased (Fig. 21) compared to the only 2.5% SDP and 2.5% CHP samples. Furthermore, strength exhibited a decreasing trend (Table 9), although, they met the standard criteria. This is again the

fact that the calcium oxide (CaO) in the ESP interacts with water to produce portlandite ( $\text{Ca(OH)}_2$ ), which then reacts with silica ( $\text{SiO}_2$ ) in the clay to form calcium silicate hydrate ( $\text{CaSiO}_3 \cdot 2\text{H}_2\text{O}$ ) which gives the materials their strength. However, when clay was substituted by SDP/CHP in a mixture, the amount of silica ( $\text{SiO}_2$ ) available to react with portlandite  $\text{Ca(OH)}_2$  decreased, and unreacted portlandite had a detrimental influence on strength [111]. Fig. 22 and Fig. 23 present the XRD analysis of the Eggshell-Sawdust and Eggshell-Coconut husk samples. Moreover, the UPV results presented in Fig. 24 revealed that when the amount of ESP increased with SDP/CHP, velocity declined, indicating the formation of more porous

1 materials. Similar to the results of the first phase UPV is  
2 directly related to the strength values (Fig. 25(a) and Fig.  
3 25(b)). Regarding the durability test, the samples  
4 showed a slight increase in erosion rate compared to the  
5 only 2.5% SDP and 2.5% CHP samples (Table 10).

6 Besides, according to visual inspection following the  
7 water spray test, the reference sample displayed multiple  
8 surface cracking, where the other samples from the first  
9 and second phases had smoother surfaces (Fig. 26).

## 6. Conclusions

This study evaluates the potential use of eggshell powder, sawdust powder and coconut husk powder in the production of unfired clay blocks. The

physico-mechanical and durability properties such as density, linear shrinkage, capillary water absorption, flexural strength, compressive strength, ultrasonic pulse velocity test, drip test and water spray test were investigated. Experimental tests conducted on unfired clay blocks revealed the following conclusions:

1. When the amount of the waste materials was increased in the mixture the density of the samples gradually decreased. However, all the ESP incorporated samples reached the minimum value of 1750 kg/m<sup>3</sup> required by the Indian Standard: IS 1725 and Sri Lankan Standard: SLS 1382 for the load-bearing blocks. For SDP and CHP additives, only 2.5% content achieved the standard requirement. Other percentages can be used to produce lightweight masonry blocks.

2. The XRD analysis indicated that there was no reaction when SDP and CHP were mixed with clay. In the presence of water, however, ESP reacted with clay to create cementitious material, significantly improving the properties of the samples.

3. The linear shrinkage decreased with the addition of ESP and SDP but increased with CHP addition. Besides, the capillary water absorption coefficient decreased for ESP addition up to 40% and then increased for the higher amount. For the SDP and CHP samples, the capillary water absorption gradually increased with increasing the waste percentage.

4. In terms of mechanical properties, after 28 days, all the waste-incorporated samples fulfilled the minimum compressive strength (1 MPa-2.80 MPa) and flexural strength requirement (0.25 MPa-0.50 MPa) of the standards. ESP samples showed higher compressive

and flexural strength values (FS: 2.24 MPa, CS: 5.68 MPa) compared to SDP (FS: 2 MPa, CS: 4.74 MPa) and CHP (FS: 2.14 MPa, CS: 4.78 MPa) samples. However, combining ESP with SDP and CHP resulted in a loss of strength.

5. It was noticed that the UPV measurements followed a similar pattern to the strength. The samples with the highest compressive strength of each group were found to have the highest UPV values, with 40% ESP, 2.5% SDP and 2.5% CHP.

6. According to New Zealand standard NZS 4298, all samples passed the drip test and water spray test, where an erodibility index of 2 was recorded, suggesting that they are "slightly erodible." The results showed that when ESP, SDP and CHP were added individually and in combination with clay, erosion resistance improved compared to the reference sample.

The results of this experiment revealed that ESP, SDP and CHP can be used to stabilise unfired clay blocks because they improved the samples' overall properties. Moreover, the results of the tests may be useful in finding a solution to the waste management problem as well as providing potential low-cost materials for the construction sector.

## Acknowledgments

The authors acknowledge the School of Civil Engineering and Built Environment at Liverpool John Moores University, United Kingdom for the financial support and gratefully thank the laboratory technicians for their appreciable assistance.
