ABSTRACT

We present photometric and spectroscopic data of the unusual interacting supernova (SN) 2021foa. It rose to an absolute magnitude peak of $M_r = -18$ mag in 20 days. The initial light curve decline shows some luminosity fluctuations before a long-lasting flattening. A faint source ($M_r \sim -14$ mag) was detected in the weeks preceding the main event, showing a slowly rising luminosity trend. The r -band absolute light curve is very similar to those of SN 2009ip-like events, with a faint and shorter duration brightening (‘Event A’) followed by a much brighter peak (‘Event B’). The early spectra of SN 2021foa show a blue continuum with narrow (~ 400 km s⁻¹) H emission lines that, two weeks later, reveal a complex profile, with a narrow P Cygni on top of an intermediate-width (~ 2700 km s⁻¹) component. At +12 days, metal lines in emission appear and He I lines become very strong, with He I $\lambda 5876$ reaching half of the $H\alpha$ luminosity, much higher than in previous SN 2009ip-like objects. We propose that SN 2021foa is a transitional event between the H-rich SN 2009ip-like SNe and the He-rich Type Ibn SNe.

Key words. supernovae: general – supernovae: individual: SN 2021foa

1. Introduction

Supernovae (SNe) that explode within a dense and massive circumstellar medium (CSM) are called ‘interacting’ SNe (Fraser 2020). If the CSM is H-rich, they are Type IIn SNe (Schlegel 1990; Filippenko 1997), and their spectra show narrow Balmer emission lines. If the CSM is He-rich, they are classified as Type Ibn SNe (Matheson et al. 2000; Pastorello et al. 2008a; Hosseinzadeh et al. 2017), and strong emissions from He I lines are present.

Among SNe IIn, SN 2009ip (Pastorello et al. 2013; Fraser et al. 2013, 2015; Margutti et al. 2014; Mauerhan & Williams 2014; Graham et al. 2014, 2017) and similar objects¹ are characterised by a wide variability or recurrent outbursts in the years prior to the explosion. SN 2009ip has a double-peak light curve with a first luminous ($M_r \sim -15$ mag) maximum just a few weeks before the brightest one ($M_r \sim -18$ mag). These peaks are often referred to as ‘Event A’ and ‘B’, respectively (Pastorello et al. 2013).

The second major class of interacting SNe are Type Ibn. Their light curves usually fade rapidly after peaking, and their spectra are dominated by narrow lines of He I and very weak or no H lines. Transitional Type Ibn/IIn SNe that show both H and He I lines, with the He lines having strengths comparable to the H ones, have also been discovered (Pastorello et al. 2008b, 2015; Smith & Mauerhan 2012; Hosseinzadeh et al. 2017).

In this Letter we present the photometric and spectroscopic follow-up campaign of SN 2021foa, an interacting SN with

a photometric evolution almost identical to SN 2009ip-like objects. It has a complex $H\alpha$ line profile, but also strong He I emission lines.

2. Discovery and host galaxy

SN 2021foa (also known as ASASSN-21dg, ATLAS21htp, and PS21cae) was discovered by the All Sky Automated Survey for SuperNovae (ASAS-SN; Shappee et al. 2014) on 15 March 2021 (MJD = 59288.45) at a Sloan- g apparent magnitude of 15.9, with the last non-detection 10 days earlier, at $g = 17.9$ mag (Stanek & Kochanek 2021). However, ASAS-SN detected it on 9 March at $g = 17.6$ mag and observed a six-day rise to $g = 15.9$ mag², when the discovery was reported. Its coordinates are $\alpha = 13:17:12.29$, $\delta = -17:15:24.19$ (J2000). SN 2021foa was classified by Angus (2021). The host galaxy IC 863 is a barred spiral, with a redshift of $z = 0.008386$ (Pisano et al. 2011). The NASA/IPAC Extragalactic Database³ reports a kinematic distance, corrected for the Virgo infall, of $d = 34.8 \pm 2.4$ Mpc ($\mu = 32.71 \pm 0.15$ mag), which we adopt as the distance to IC 863. The Milky Way reddening towards IC 863 is $A_V = 0.224$ mag (Schlafly & Finkbeiner 2011). From spectroscopic considerations (see Appendix A) we infer the presence of an additional host galaxy extinction of $A_V(\text{host}) \approx 0.40 \pm 0.05$ mag.

3. Photometric evolution

Our multi-band follow-up campaign started soon after the discovery and lasted for 6 months. We collected *Swift* ultraviolet

¹ SN 2010mc (Smith et al. 2014), SN 2011fh (Pessi et al. 2022), LSQ13zm (Tartaglia et al. 2016), SN 2015bh (Elias-Rosa et al. 2016; Thöne & de Ugarte Postigo 2017), SN 2016bdu (Pastorello et al. 2018), and AT 2016jbu (Kilpatrick et al. 2018; Brennan et al. 2022a,b).

Fig. 1. Light curves of SN 2021foa. *Left:* UV, optical, and NIR light curves of SN 2021foa, covering 6 months of observations. The phases are relative to the V -band maximum. The pre-discovery detections are also reported. The discovery epoch is marked with a vertical line. *Right:* comparison of the r -band absolute light curves of SN 2021foa, AT 2016jbu, and SN 2009ip (R -band). The error bars include the uncertainties on the photometric measurements, the distance, and the reddening in quadrature. The vertical lines mark the significant phases: ‘Event A’, ‘Event B’, the ‘plateau’, and the ‘knee’. The ATLAS pre-discovery orange-band detections of SN 2021foa are also shown with square symbols to point out its Event A. The R -band absolute light curves of the Type IIn SN 1996al, the Type Ibn SN 2006jc, and the transitional IIn/Ibn SN 2005la are also plotted.

(UV) and ground-based optical and near-infrared (NIR) photometric data with a plethora of telescopes and instruments, which are listed in Table B.1.

The optical and NIR photometric data were reduced using standard procedures with the dedicated SNOoPY pipeline (Cappellaro 2014, see Reguitti et al. 2019 for a description of the procedures). The UV data were reduced with the HEASOFT pipeline⁴. The final UV, optical (Sloan, Johnson, and ATLAS), and NIR magnitudes are listed in Tables B.2–B.6, and the light curves are plotted in the left panel of Fig. 1.

The CHilean Automatic Supernova Search Survey project (Pignata et al. 2009) monitored the field of IC 863 between 2008 and 2015, and the Palomar Transient Factory (Law et al. 2009) scanned it between 2009 and 2014. We inspected their archival images in search of signatures of pre-explosion activity from the progenitor of SN 2021foa but found no evidence of variability. The Pan-STARRS1 (Chambers et al. 2016) survey also observed the sky region of IC 863 in the years 2013–2020, providing only deep (~ 22 mag) non-detections, which allow us to estimate upper limits to the pre-explosion progenitor’s variability. Instead, the Asteroid Terrestrial-impact Last Alert System (ATLAS; Tonry et al. 2018) survey detected the 12-day rise of a faint source (from ATLAS-cyan (c) ~ 20.4 to ~ 18.8 mag) at the position of SN 2021foa beginning on 10 February 2021, 43 days before the discovery, that then remained nearly constant at ATLAS-orange (o) ~ 19 mag for 3 weeks.

We observed a rise in the first four *Swift* epochs. By fitting a second-order polynomial to the data, we found that the UV maximum was reached about 5 days after discovery, while in the optical the peak was reached between 3 and 6 days later, in the B and z band, respectively. The V -band maximum was reached on MJD = 59301.8 ± 0.1 , and we adopted this as a reference epoch. The V -band peak absolute magnitude is $M_V = -17.8 \pm 0.2$ mag. The light curves are remarkably similar in the different bands: after maximum, the luminosity of the object starts to decline before settling into a plateau (for ~ 10 days, between +13 and +22 d) at about 1 mag fainter than the peak (less in redder bands,

e.g., 0.5 mag in z). Following the plateau, the light curves display a rapid and linear decline, lasting ~ 2 months, with a faster decay in the blue filters compared to the red ones. The latest observed magnitudes are slightly fainter than the pre-discovery ATLAS ones. The NIR light curve evolution follows that of the redder optical bands (although the NIR campaign lasted only 2 months). After +80 d, a flattening is observed in the r , iz , cyan, and orange light curves. The ATLAS observations continued up to +130 d, when they were stopped because the object was too close to the Sun.

As shown in the right panel of Fig. 1, we find a remarkable similarity between the r -band absolute light curves of SN 2021foa and SN 2009ip during the brightest event (Pastorello et al. 2013; Fraser et al. 2013), as well as with that of the SN 2009ip-like object AT 2016jbu (Kilpatrick et al. 2018; Brennan et al. 2022a). Comparing them with those of the H-rich Type IIn SN 1996al (Benetti et al. 2016), the He-rich SN 2006jc (Pastorello et al. 2007), and the transitional IIn/Ibn SN 2005la (Pastorello et al. 2008b), we see that the decline rate of SN 2021foa is intermediate between the H- and He-rich SNe. The faint ATLAS pre-discovery detections (at $M_o \sim -14$ mag) correspond to the ‘Event A’, while the brighter post-discovery light curve peak is the ‘Event B’. The ‘plateau’ at +20 d is more pronounced in SN 2021foa, while the ‘knee’ occurs slightly earlier (+40 d instead of 45 d) and is less noticeable. Finally, both AT 2016jbu and SN 2021foa show a much slower decline in their light curves, roughly from +70 d onwards.

4. Spectral evolution

We also conducted a spectroscopic follow-up of SN 2021foa, during which we collected 19 optical spectra that span the first 3 months of evolution. The log of spectroscopic observations is provided in Table B.7, and the time series is presented in the left panel of Fig. 2. The spectra from the ‘Copernico’ telescope, the Nordic Optical Telescope (NOT), and the Gran Telescopio Canarias (GTC) were reduced, extracted, and calibrated with slightly different versions of the FosCGui⁵ pipeline

⁴ NASA High Energy Astrophysics Science Archive Research Center – Heasarc 2014.

Fig. 2. Spectra of SN 2021foa. *Left:* sequence of spectra of SN 2021foa. The spectra are redshift- and reddening-corrected. The principal identified lines are marked, as are the telluric absorption bands. The phases indicated are relative to the *V*-band maximum. For a better visualisation, the fluxes of the late spectra are multiplied by the factor reported in parentheses. *Right:* zoomed-in view of the H α line at three representative epochs, -10 d, +37 d, and +79 d, to highlight the evolution and the complexity of its profile. In abscissa are the rest-frame velocities.

(Cappellaro 2014), adapted for instruments attached to each telescope. The spectra from the Telescopio Nazionale *Galileo* (TNG) were reduced with the standard procedures under the PyRAF environment. The final spectra were flux-corrected using the nearest, in time, available photometry.

The early spectra show a blue and hot continuum with a black-body temperature, T_{BB} , of 15 000 K and narrow H lines in emission, as typically observed in SNe IIn. He I lines ($\lambda 4471$, $\lambda 5015$, and $\lambda 5876$) are present but weak. Two days later (at -10 d), we took a mid-resolution spectrum. In this spectrum, the H β , H γ , and H δ lines start to develop a narrow P Cygni absorption on top of the intermediate component. From H β , the position of the P Cygni minimum corresponds to an expansion velocity of 500 km s⁻¹. We used the Image Reduction and Analysis Facility (IRAF⁶) task `splot` to separate the H α profile into two Gaussian components: a narrow component with a full-width at half maximum (FWHM) velocity⁷ of 400 km s⁻¹ and an intermediate one of 2700 km s⁻¹.

From the 3 days before the *V*-maximum spectrum onwards, H α starts to show a narrow P Cygni absorption profile. At this

epoch, T_{BB} has dropped to 12 000 K. Two weeks after the maximum, the spectrum dramatically changes: in the blue part, emission lines from metals appear, mostly with P Cygni profiles (such as the multiplet 42 of Fe II $\lambda\lambda 4924$, 5018, and 5169), and He I lines are now very strong, particularly $\lambda 5876$, with a flux that is close to half that of H α . A deep absorption feature is visible on top of the He I $\lambda 5876$ line. The Balmer lines also reveal P Cygni absorptions, up to H ϵ . The narrow P Cygni absorption of H α is now evident, and the intermediate-width component has turned into a broad one, with a FWHM velocity (v_{FWHM}) of ~ 8000 km s⁻¹.

Later, the P Cygni profiles tend to disappear (except H α), the metal lines broaden, and the He I lines remain strong (at +12 d, we measure the following flux ratios: He I $\lambda 5876$ /H α $\approx 1/2$ and He I $\lambda 7065$ /H α $\approx 1/4$). At +30 d, the lines become more prominent relative to the continuum and broaden, with a mean v_{FWHM} of ~ 5000 km s⁻¹. The P Cygni absorption in H α is less evident, and H β weakens. The He I lines are still more prominent than most Balmer lines, and a broad double-peak bump from the Ca II NIR triplet emerges, as does a feature around 7300 Å that can be attributed to [Ca II] $\lambda\lambda 7291$, 7324, as its profile is comparable to that of the Ca II NIR triplet or, alternatively, He I $\lambda 7281$. Furthermore, a broad and strong emission centred at 4600 Å is present in the blue part, possibly due to Fe II. The temperature has cooled to $T \sim 7000$ K, based on the peak of the continuum flux.

In the +37 d mid-resolution spectrum, we de-blended H α into broad emission ($v_{\text{FWHM}} \sim 6000$ km s⁻¹), narrow emission

⁶ IRAF is distributed by the National Optical Astronomy Observatory, which is operated by the Association of Universities for Research in Astronomy (AURA) under a cooperative agreement with the National Science Foundation.

⁷ Corrected for instrumental resolution, i.e., $FWHM_{\text{corrected}} = \sqrt{FWHM_{\text{observed}}^2 - FWHM_{\text{instrument}}^2}$.

Fig. 3. Spectral comparison at a similar phase (around 1.5 months after the V -band maximum) of SN 2021foa, Type IIc SNe 2013gc and 1996al, SN 2009ip and the 2009ip-like event AT 2016jbu, the prototypical Type Ibn SN 2006jc, and the transitional Type Ibn/IIc SNe 2005la and 2011hw. Different colours indicate different SN types: SN 2009ip-like in blue, SNe IIc in red, transitional Ibn/IIc in green, and Ibn in purple.

($v_{FWHM} \approx 450 \text{ km s}^{-1}$), and a narrow P Cygni absorption, which has a velocity at the minimum position that is consistent with the FWHM of the narrow emission component. A red shoulder of $H\alpha$ is consistent with the emerging He I $\lambda 6678$ line. The He I $\lambda 7065$ line has a trapezoidal shape, with $v_{FWHM} \sim 6000 \text{ km s}^{-1}$. At about 2 months after the maximum, the He I lines weaken, with He I $\lambda 5876/H\alpha \approx 1/3$, and the P Cygni absorption on top of $H\alpha$ becomes less pronounced.

5. Discussion and conclusion

The complex Balmer emission line profiles in SN 2021foa, especially $H\alpha$ (Fig. 2, right panel), with the simultaneous presence of multiple emission components and a narrow P Cygni absorption, are a distinctive characteristic of a subclass of SNe IIc sometimes labelled as SNe IIc (Benetti 2000; Benetti et al. 2016; Reguitti et al. 2019). SN 2009ip-like events also reveal a similar structured profile, though they do not show strong He I lines. In Fig. 3 we compare the spectral region 4500–7500 Å of SN 2021foa, two SNe IIc (SNe 2013gc and 1996al), SN 2009ip (Pastorello et al. 2013), and AT 2016jbu (Brennan et al. 2022a) at about 1.5 months after the V -band maximum. We note that the $H\alpha$ profiles are quite similar, while the He I lines in SN 2021foa are much stronger than those of the comparison objects.

Conversely, the blue part of the spectra of SN 2021foa and the strength of the He I lines resemble those of He-rich Type Ibn SNe (Pastorello et al. 2007; Hosseinzadeh et al. 2017). Two notable objects are SN 2011hw (Smith & Mauerhan 2012; Pastorello et al. 2015), a transitional SN Ibn/IIc that shows an $H\alpha$ emission in an otherwise He-dominated spectrum, and SN 2005la (Pastorello et al. 2008b), in which $H\alpha$ is even stronger than the He lines. In both objects, an Ofpe/WN9, in transition from a luminous blue variable (LBV) to an early H-poor but not H-free Wolf-Rayet (WR) star, was suggested as a progenitor. In the lower part of Fig. 3, SN 2021foa is com-

pared with the Type Ibn SN 2006jc (Pastorello et al. 2007) and the transitional Ibn/IIc SNe 2005la and 2011hw. These objects show a progressive strengthening of the $H\alpha$ emission, though the He I lines remain prominent. SN 2021foa may be part of a bridge connecting H-rich SN 2009ip-like and Type Ibn SN events, indicating the possible existence of a continuum in properties, mass-loss history, and progenitor types between these two types of peculiar transients. The host galaxy metallicity plays an important role in the mass-loss history of massive stars, as a metal-poor environment is expected to inhibit mass loss in massive stars, in contrast with what happens with metal-rich environments. Indeed, the metallicity near the site of SN 2021foa (see Appendix A) is roughly solar.

The outer envelope of the progenitor of SN 2021foa was still H-rich, as at late phases $H\alpha$ emission remains the predominant spectral feature, but a larger fraction was lost with respect to SN 2009ip. The suggested progenitors of SN 2009ip-like events are H-rich LBV stars (Smith et al. 2010, 2014; Foley et al. 2011b; Mauerhan & Smith 2013, but see Brennan et al. 2022b). Type IIc SNe are probably connected to those objects by having similar progenitors, but they probably have a different mass-loss history or are observed with a different orientation. The supposed progenitors of SNe Ibn are H-poor WR stars (Foley et al. 2011a), but Sun et al. (2020) concluded that SNe Ibn can originate from lower-mass stars ($M < 12 M_{\odot}$) in interacting binaries. The detonation of a helium white dwarf scenario was also proposed (Sanders et al. 2013; Hosseinzadeh et al. 2019). As SN 2021foa shares photometric and spectroscopic properties with SN 2009ip and SNe IIc, but with strong He I lines that resemble the spectra of Ibn/IIc SNe, the progenitor of SN 2021foa could have been an LBV on the way to becoming a WR star. The star has likely lost a large fraction of its H envelope, although a residual H layer is still retained. The wind velocity derived from $H\alpha$ ($\sim 450 \text{ km s}^{-1}$) is relatively low for a classical WR. While this is consistent with the wind velocity from an LBV (e.g., Vink 2018), it is also compatible with the wind from a WNH star (Smith 2017) and is similar to that observed for SN 2005la (Pastorello et al. 2008b).

The upcoming 10-year Legacy Survey of Space and Time at the *Vera Rubin* Telescope will discover hundreds of transitional objects. Statistical studies of transients similar to SN 2021foa and their environments will enable us to elucidate their uncertain nature.

Appendix A: Host galaxy metallicity and reddening

From our long-slit spectroscopy of SN 2021foa at a late phase, we extracted the spectrum of an H II region adjacent to the SN. The spectrum shows typical narrow emission lines from ionised gas, including $H\alpha$, [N II], and [S II]. Assuming that the adjacent H II region is representative of the SN explosion site, we measured the emission line flux of $H\alpha$ and [N II] $\lambda 6584$ in its spectrum to derive the oxygen abundance as a metallicity proxy, via the N2 index according to the Marino et al. (2013) calibration, and also the [S II] $\lambda 6717, 6731$ doublet for the same purpose using the Dopita et al. (2016) scale. The measured metallicity in $12+\log(O/H)$ is 8.59 dex (N2) and 8.66 dex. Within the typical metallicity calibration error of 0.1-0.2 dex, these values agree with each other. The derived metallicity is thus consistent with being nearly solar ($12+\log(O/H)_\odot = 8.69$ dex; Asplund & Grevesse 2009).

The estimate of the line of sight reddening is a crucial step for the characterisation of a stellar transient. One of the most popular ways to estimate this value is through the detection of narrow interstellar lines. Turatto et al. (2003) proposed inferring the colour excess using a linear relation with the equivalent width (EW) of the Na I $\lambda\lambda 5890, 5896$ doublet. Poznanski et al. (2012) revised the relation using the individual line components in higher resolution spectra.

In our early spectra of SN 2021foa, a narrow absorption of the Na I doublet is visible on top of the He I $\lambda 5876$ line at the host galaxy redshift, with $EW=0.8\pm 0.1$ Å. The Poznanski et al. (2012) relation between sodium absorption and dust extinction saturates at EWs beyond 0.8 Å, and hence we estimated the internal extinction using the Turatto et al. (2003) formula, which provides an additional reddening of $A_V(host) \approx 0.40 \pm 0.05$ mag.

In Fig. A.1 we show the evolution of the profile of the narrow (interstellar) Na I D feature in the velocity space. While its EW remains roughly constant (within the measurement errors) until +45 d, it seems to significantly increase in the late-time spectra. However, the change in the relative intensities of the broader features of He I $\lambda 5876$ and Na I D (attributed to the SN ejected material) hinders a reliable estimate of the EW of the interstellar Na I D component, and probably explains its apparent evolution without needing to invoke changes in the ionisation state of the interstellar medium. Indeed, in the last spectrum the minimum of the P Cygni absorption component of Na I D is blueshifted by about 400 km s^{-1} , which is about the same amount as in $H\alpha$. This indicates that both the narrow interstellar absorption and the P Cygni line of the transient contribute to the observed Na I D profile. As a consequence, in this paper we assume that the EW

Fig. A.1. Evolution of the profile of the Na I absorption with time, in velocity space.

of the Na I D absorption measured only in the early spectra is entirely produced by interstellar gas and can be used as a proxy to estimate the reddening contribution of the host galaxy.
