KEY WORDS

Ethnicity; doctor; patient; mental wellbeing; personal care plan
Abstract

Objective: There is limited understanding of ethnic inequalities in doctor-patient communication regarding personal care plans (PCPs). This study investigated the mediating effects of positive mental wellbeing on differences in PCP-related doctor-patient communication amongst South Asian and Caucasian UK residents.

Design: Data from 10980 respondents to the 2013 Health Survey for England was analysed using bootstrapping methods. Constructs from the WEMWBS (Warwick and Edinburgh Mental Wellbeing Scale) (Stewart-Brown and Janmohamed 2008) were assessed as mediators of relations between ethnicity and several doctor-patient communication variables, including PCP-related interactions; (a) had a PCP-related discussion about a long-term condition with a doctor/nurse, and (b) had this conversation within the past year, (c) agreed to a PCP with a health professional; and (d) talked to a doctor in the past 2 weeks.

Results: Bootstrapped mediation analysis (Hayes 2013) showed that three positive mind-sets mediated associations between ethnicity and doctor-patient contact, including PCP-related communication. Being able to make up one’s mind ($ab = -0.05; BC_a CI [-0.14, 0.01]$) mediated the effect of ethnicity on agreeing to a PCP, while having energy to spare ($ab = 0.07; BC_a CI [-0.04, 0.12]$), and feeling good about oneself ($ab = 0.03; BC_a CI [0.01, 0.07]$), mediated ethnic effects on talking to a doctor during the past fortnight. The mediating effect of reported energy persisted after controlling for medical history, perceived health, and other covariates.
Conclusions: Ethnic disparities in doctor-patient interaction, including PCP-related communication, are partly explained by positive mental wellbeing. Gauging positive psychological moods in patients, particularly self-worth, self-perceived vigour and decisiveness, are relevant to addressing ethnic inequalities in doctor-patient communication. As PCPs may have direct implications for patient health it is important for health professionals to address deficits in psychological functioning that may precipitate ethnic inequalities in setting up PCPs.

KEY WORDS
Ethnicity; doctor; patient; mental wellbeing; personal care plan
1. Introduction

Doctor-patient consultations can be stressful for patients (Gallan et al. 2013, Cegala, Street, and Clinch 2007). This can be particularly so when patients are required to set up a personal care plan (PCP) in order, for example, to effectively manage a chronic health condition (Jansen, Heijmans, and Rijken 2015), recover from an illness/injury (Tarkin, Sop, and Pape 2008), or simply to cope with stress (Tvrdik et al. 2015). A PCP is a written document that identifies specific treatment goals for a patient (e.g., 5% less blood sugar) and activities to achieve them (e.g., taking medication). The plan is agreed to by the patient and their doctor, or health care team (Coulter, Roberts, and Dixon 2013). Having a PCP has been implicated in improved health outcomes for patients (Hird et al. 2015, Coulter et al. 2015). Nevertheless, setting up a PCP can be challenging for patients because it may involve prolonged (and periodic) doctor-patient consultations, during which potentially difficult
treatment decisions have to be made, and/or challenging goals need to be agreed to, subject to
review at a later date (Diabetes UK 2009). For patients, having a positive mood in this
context can facilitate adaptive coping processes (e.g., focusing on problem solving) that
enable a more productive dialogue with a health professional (Folkman 1997, Edwards and
Cooper 1988).

Positive mental wellbeing broadens an individual's range of thoughts and actions (e.g.,
making new friends), which in turn builds enduring physical, social, and intellectual
resources (e.g., being more polite) (Fredrickson 1998, 2001, 2004, Fredrickson et al. 2008).
This can have significant benefits for PCP-related liaisons (Ogrodniczuk, Piper, and Joyce
2008). For example, evidence suggests positive-minded patients interact more with health
professionals (Gallan et al. 2013). By contrast, less expression of positive emotion in patients
has been associated with more negative dispositions in doctors (Ogrodniczuk, Piper, and
Joyce 2008). Nevertheless, despite the potential value of good mental wellbeing for
satisfactory doctor-patient liaisons (Ogrodniczuk, Piper, and Joyce 2008, Paternotte et al.
2015), and health outcomes in general (Dubois et al. 2012, Edwards and Cooper 1988,
Casellas-Grau, Font, and Vives 2014), it is unclear how positive moods affect PCP-related
doctor-patient interactions.

Mental wellbeing may be particularly relevant in intercultural consultations to reach a
PCP agreement (Paternotte et al. 2015). Studies suggest ethnic inequalities in doctor-patient
interactions (Burt et al. 2016, Volz, Moore, and Belkora 2015, Ahmed et al. 2015, Croker et
people of South Asian descent generally report poorer doctor-patient experiences compared
with Caucasians (Ahmed et al. 2015, Burt et al. 2016). An analysis of data from the *English
GP Patient Survey* (including 190,582 patients across 1,068 practices) found that
Bangladeshi, Pakistani, and Indian patients reported worse doctor-patient communication,
compared with White British patients. Another study (data from 1,599,801 respondents) found significant differences in doctor-patient interactions between White British responders, and those of Pakistani and Bangladeshi descent (Burt et al. 2016). South Asians reported more negative experiences (e.g., degree of involvement in decision making, having tests/treatments explained). This ethnic difference was magnified amongst older and female respondents, suggesting age and gender play an important role.

A recent systematic review of the literature in this area identified negative psychological factors (e.g., perceived prejudice) affecting intercultural doctor-patient interactions (Paternotte et al. 2015). While evidence suggests positive mental wellbeing can help improve the patients’ experience (Folkman 1997, Edwards and Cooper 1988, Salovey et al. 2000, Fredrickson 1998), it is unclear to how this applies to PCP consultations, particularly in an intercultural context (Paternotte et al. 2015). A qualitative study of South Asian adults diagnosed with diabetes found that participants made limited contact with their doctor during fasting (Patel et al. 2015), suggesting any necessary PCP-related communication is unlikely to have taken place. Psychological dispositions were generally negative (e.g., anxiety), suggesting a more positive mind-set might play an important mediating role, for example, by motivating patients to contact their doctor (Fredrickson 1998, Edwards and Cooper 1988, Folkman 1997). However, to the best of my knowledge, no study has tested this proposition.

Existing literature is constrained by the fact that most studies examine the direct role of ethnicity (Ahmed et al. 2015, Burt et al. 2016), and/or mental wellbeing (Butalid, Bensing, and Verhaak 2014, Bahremand et al. 2016). It isn’t possible to extrapolate mediation from current evidence, as the requisite analytical conditions aren’t usually met (Hayes 2013, 2009). The picture is further compounded by the focus on negative mental wellbeing (e.g., dissatisfaction, perceived prejudice) (Paternotte et al. 2015), and narrowly defined ‘patient’ groups (e.g., people recently registered with and/or presenting for treatment at a clinic or
hospital) (Burt et al. 2016). Regarding the latter point, most British residents have consulted a health professional fairly recently (87% have seen their doctor in the past year) (IPSOS MORI 2015), and hence can be considered ‘patients’ depending on the criteria used (Wolf et al. 2014). The majority (59%) have been involved in planning their treatment and care (IPSOS MORI 2015). Although PCPs are formally offered to people with long-term medical conditions (Diabetes UK 2009), PCPs may also be discussed with people experiencing stress (Tvrdik et al. 2015), or struggling with substance abuse (Hassan et al. 2009). Thus, it is important to understand intercultural PCP-related consultations in a broad context that involves the wider public, rather than a specific narrowly defined ‘patient’ group (Wolf et al. 2014).

Evidence for mediation would suggest it is a person’s positive state of mind, rather than their cultural background per se, that directly accounts for ethnic disparities in PCP-related communication. A positive mood may serve as a proxy variable, delineating psychological interventions that help improve intercultural doctor-patient experiences. Thus, the present study aimed to explore the notion that ethnicity predicts mental wellbeing, which in turn predicts doctor-patient communication regarding PCPs. The study focused specifically on South Asians and Caucasians, as these groups have shown reliable disparities in doctor-patient interactions (Burt et al. 2016, Ahmed et al. 2015). Previous research suggests the frequency of contact with health service providers may be a particular problem with South Asian patients (Commander et al. 2004, Szczepruta, Price, and Gumber 2008, Marlow, Waller, and Wardle 2015). For example, South Asian patients of Muslim faith have been found to make limited contact with their doctor during fasting (Patel et al. 2015). When South Asian patients do make contact, they may be less involved in decisions about their care (Ahmed et al. 2015, Burt et al. 2016). Thus, the frequency of doctor-patient contact, and also their ability to agree to a care plan, are critical in understanding ethnic differences in this
context. Given evidence implicating mental wellbeing in doctor-patient consultations (Paternotte et al. 2015), and the experiences of South Asians in this context (Patel et al. 2015), we hypothesised that positive psychological attributes mediate ethnic disparities in PCP-related communication.

2. Methods

2.1 Sample & procedure

This study analysed archived cross-sectional data from the 2013 Health Survey for England (HSE) national survey (Health Survey for England 2013). The HSE is an annual survey to monitor the health of the general public in England UK. It is managed by the Central Health Monitoring Unit, which is part of the UK Department of Health. The survey is conducted annually and data is collected from a representative sample of peoples (aged 16 years and over) living in private residential addresses. All eligible individuals in a household (a maximum of 10) are invited to undergo an interview, and undertake height and weight measurements. During each interview participants are asked structured questions about their health, use of health services, and lifestyle. Adults filled in a self-completion questionnaire booklet incorporating the WEMWBS (Warwick-Edinburgh mental well-being scale) (Tennant et al. 2007, Stewart-Brown et al. 2009) and other measures. This interview is followed shortly thereafter by a nurse visit, to conduct more measurements and collect more (primarily biomedical) data. The study reported here analysed data from the 2013 survey, with a sample size of 10980 participant records. The mean age was 41.35 years (SD 23.99). There were 5955 (54.2%) females and 5025 (45.8%) males.
2.2 Doctor-patient communication

The primary focus here was the frequency of doctor-patient communication specifically relating to PCPs. The occurrence of such doctor-patient contact was depicted in a number of questions on PCP’s and use of health services (Health Survey for England 2013). The interviewer read out the following statement, ‘You mentioned earlier that you have a/some long term health condition(s). Doctors, nurses or other health workers sometimes have a special discussion with people with a long term condition, to look at the way that their health and care is managed. This is to make sure that people are given information and understand the options for their condition, are happy with the care they are receiving overall for their health, and know how they can be involved in decisions about their care’. The interviewer then asked the following question: ‘Have you had a conversation like this with your doctor, nurse or health worker about your long term condition(s)?’ (‘Yes (‘1’)/ ‘No’ (‘0’)/ ‘Not sure’). If respondents answered ‘Yes’, they were then asked ‘Was this in the last 12 months or longer ago?’ (‘Longer ago’ (‘0’)/‘In last 12 months’ (‘1’)). Next, the interviewer stated, ‘Sometimes a doctor, nurse or other health worker will agree [to] a Personal Care Plan for someone with a long term condition, where they write down how the condition will be managed and who is involved in providing general health care or support’. This was followed by the question, ‘In the last 12 months, have you and a health professional agreed [to] a Personal Care Plan for your overall health and social care needs?’ (‘Yes, have agreed [to] a personal care plan <=12 months ago’ (‘1’)/‘Yes, agreed [to] a personal care plan more >12 months ago’ or ‘No, do not have a personal care plan’ (both scored ‘0’)). The interviewer also asked about service use, ‘The next few questions are about your GP and how often you use certain health services. During the two weeks ending yesterday, apart from any visit to a hospital, have you talked to a doctor on your own behalf, either in person or by telephone?’ (‘Yes (‘1’)/ ‘No’ (‘0’)). Consultations made on behalf of others were disregarded.
2.3 Mental well being

Respondents completed the WEMWBS (Stewart-Brown et al. 2009), which incorporates fourteen statements assessing positive psychological dispositions. This instrument is currently used in numerous surveys, and has generated good reliability and validity parameters (Tennant et al. 2007). Respondents first read the statement ‘Below are some statements about feelings and thoughts. Please tick the box that best describes your experience of each over the last 2 weeks’.

The statements comprise the following; ‘been feeling optimistic about the future’, ‘been feeling useful’, ‘been feeling relaxed’, ‘been feeling interested in other people’, ‘had energy to spare’, ‘been dealing with problems well’, ‘been thinking clearly’, ‘been feeling good about myself’, ‘been feeling close to other people’, ‘been feeling confident’, ‘been able to make up my own mind about things’, ‘been feeling loved’, ‘been interested in new things’, and ‘been feeling cheerful’. Responses to each statement were indicated in a five-point Likert-style scale; ‘None of the time’ (‘1’), ‘Rarely’ (‘2’), ‘Some of the time’ (‘3’), ‘Often’ (‘4’), and ‘All of the time’ (‘5’). Together, these fourteen items generated high internal consistency (α = 0.91). Nevertheless, it was decided to treat the statements as single item measures, for several reasons: (a) weak effect sizes were expected, (b) the items were highly homogeneous (α > 0.90), (c) items were semantically redundant (due to high internal consistency), which can negatively affect multiple item measures, and (d) the population was diverse (Diamantopoulos et al. 2012, Fuchs and Diamantopoulos 2009). Although multi-item measures can outperform single items when the sample size is over a certain cut-off (e.g., N > 50) (Diamantopoulos et al. 2012), both approaches may perform equally well with very large samples (Cheung and Lucas 2014).
2.4 Health status

General health status was gauged by various queries (Health Survey for England 2013), starting with the question *'How is your health in general? Would you say it was...?*', ‘Very good’ (‘1’), ‘Good’ (‘2’), ‘Fair’ (‘3’), and ‘Bad’ (‘4’), or ‘Very bad’ (‘5’). The interviewer then read the following statement, *'This question asks you about any health conditions, illnesses or impairments you may have. Do you have any physical or mental health conditions or illnesses lasting or expected to last 12 months or more?*’ (‘Yes (‘1’)’/ ‘No’ (‘0’)). The researcher then recorded up to six conditions or illnesses. This information was organised into the following categories, ‘No longstanding illness’ (‘0’), ‘One longstanding illness’ (‘1’), or ‘Two or more longstanding illnesses’ (‘2’).

2.5 Ethnicity

Ethnic status was derived from eighteen ethnic categories (Health Survey for England 2013): Respondents who self-identified as ‘White’ (English/Welsh/Scottish/Northern Irish/British), ‘White –Irish’, ‘White – Gypsy or Irish Traveller’ or ‘Any other White background’ were classified as ‘Caucasian’ (scored ‘1’). Individuals who identified themselves as ‘Indian’, ‘Pakistani’, or ‘Bangladeshi’ were labelled as ‘South Asian’ (scored ‘0’).

3. Results

Data analysis was based on bootstrapping, using the PROCESS (version 2.15) SPSS add-on for statistical mediation analysis (Hayes 2013). Ethnicity was entered as variable ‘X’ (i.e., *Predictors*), while the four doctor-patient variables were each treated as variable ‘Y’ (i.e., *Outcomes*), in separate models. The fourteen WEMWBS items were each entered as variables ‘M’ (i.e., the *mediators*). These variables were analysed in two ‘blocks’; the first block containing the first ten items from the WEMWBS, and the second block comprising the
remaining four attributes (the PROCESS software can only analyse a maximum of 10 mediators at once). Mediation analysis evaluates three regression pathways; the effect of X on M (‘path a’); the effect of M on Y (‘path b’), and the effect of X on Y (‘path c’).

Mediation is inferred if paths ‘a’ and ‘b’ (i.e., the ‘indirect effect’, or ‘a*b’) are statistically significant. Unlike the joint significance approach to mediation (Baron and Kenny 1986), contemporary mediation analysis does not require ‘path c’ (i.e., the ‘direct effect’ of X on Y) to be significant, in order to infer mediation (Hayes 2009). In all analyses the number of bootstrap samples for bias-corrected bootstrap confidence intervals was 1000. Effect size figures for indirect effects aren’t generated for models using dichotomous outcome variables.

All analysis was performed using SPSS (version 23).

3.1 Descriptive statistics

Table 1 shows the frequency data for ethnicity, the four doctor-patient communication variables, and covariates. About two-thirds of respondents had no physical or mental health conditions or illness lasting (or expected to last) 12 months or greater. About one-fifth had one chronic illness, while just over 17% had two or more long-standing illnesses. The vast majority of respondents (almost 80%) perceived their health as ‘very good’ or ‘good’. The sample was predominantly Caucasian (over 94%), albeit the absolute number of South Asians approached 600 respondents. Over one-half of respondents had spoken with a doctor or nurse about a chronic condition, and more than two-thirds had a conversation within the past year. Over 60% did not provide valid data on making a PCP agreement. Of those who did, only about one in ten agreed to a PCP within the past year. The remainder either didn’t agree to a PCP, or reached an agreement over 12 months ago. Finally, nearly 20% provided no valid data on speaking to a doctor within the past fortnight. Of those who did, over four-fifths had talked to a doctor within the past fortnight. Table 2 shows the means and standard deviations
for mental wellbeing. The most strongly experienced dispositions were being able to make up one’s mind about things, feeling loved, and thinking clearly. Comparatively, the least experienced attributes were having energy to spare, and feeling optimistic. On average all psychological states were experienced at least ‘sometimes’. The low standard errors are consistent with the large sample size.

\[\text{Insert Table I about here}\]

\[\text{Insert Table II about here}\]

\[\text{Insert Figure 1 about here}\]

3.2 Tests for mediation

Significant a*b pathways (i.e., ‘indirect effects) only emerged in three configurations. In the first configuration there was a significant indirect effect of ethnicity on agreeing to a PCP with a health professional, through feeling able to make up one’s mind about things, \(ab = -0.05, BC_{a} CI [-0.14, -0.01]\). To determine the size of the indirect effect, I followed guidelines in the literature, whereby Cohen’s \(r\) effect size labels of 0.1 (‘small’), 0.3 (‘medium’), 0.5 (‘large’) (Cohen 1988) are first squared, since the indirect effect is a product of two pathways (a*b) (Kenny 2015). Furthermore, since X (ethnicity) is dichotomous, Cohen’s \(d\) is used for path a (thus, effect size is \(d \times r\)), so 0.02 is ‘small’, 0.15 is ‘medium’, and 0.40 denotes ‘large’ (Kenny 2015). Thus, it can be seen that the ‘completely standardised indirect effect’ (Hayes
was ‘small’ to ‘medium’. Examination of the mediator pathway reveals the nature of the indirect effect (see Figure 1). Caucasians were less likely than South Asians to feel able to make up their own minds about things (‘path a’). However, respondents who often felt able to make up their minds were less likely to have agreed to a PCP with a health professional (‘path b’). There was no direct effect of ethnicity on the outcome variable (‘path c’). The total model (i.e., the indirect effect + direct effect) was not significant. The normal theory (i.e., Sobel) tests for specific indirect effects did not demonstrate mediation. However, the Sobel test is highly conservative with high Type II error rates (Hayes 2013).

The second and third indirect effects involved the same outcome variable – talked to a doctor within the past two weeks. In the second a*b configuration, there was a significant indirect effect of ethnicity on feeling one ‘had energy to spare’, $ab = 0.07$, $BC_a CI [0.04, 0.12]$. Observation of the mediated pathway (Figure 2) showed that Caucasians were less likely to feel energetic compared with South Asians (‘path a’). However, individuals who often had spare energy were less likely to have spoken with a doctor in the past fortnight (‘path b’). In the third a*b configuration ethnicity had a significant indirect effect on the doctor-patient outcome, through the positive disposition ‘feeling good about myself’, $ab = 0.03$, $BC_a CI [0.01, 0.07]$. This mediator effect is illustrated in Figure 3. Caucasians were less likely to feel good about themselves compared with South Asians (‘path a’). However, respondents who often felt good about themselves were less likely to have communicated with a doctor recently (‘path b’). For both mediator effects the completely standardised indirect effect size ranged from ‘small to medium’. Ethnicity had no direct effect on the outcome variable in either mediator effect (‘path c’). Furthermore, the total effect of ethnicity on the outcome (i.e., indirect effect + direct effect) was not significant. Interestingly, the normal theory (i.e., Sobel) tests for specific indirect effects confirmed the bootstrapped
mediator effects of having energy to spare ($z = 3.88$, $p<0.001$), and feeling good about myself ($z = 2.40$, $p<0.05$), despite the Sobel tests high Type II error rates.

To ascertain the robustness of the observed mediator effects, it was decided to rerun the analysis controlling for existing chronic illness, self-perceived health, age and gender. A history of chronic illness has been associated with greater healthcare utilisation, in both primary and secondary settings (Palladino et al. 2016). Self-perceived health has also been implicated in this context (Thomas and Borrayo 2007). Furthermore, doctor visits become more frequent with age, and women are generally more likely to visit a health professional (Din, Zugman, and Khashper 2014). After accounting for these covariates the indirect effect of ethnicity on reaching a PCP agreement (through making up one’s mind about things) was no longer significant. Controlling for covariates also negated the indirect effect of ethnicity on the likelihood of speaking to a doctor in the past two weeks (through feeling good about oneself). However, the mediating effect of feeling energetic stayed significant, with the lower bootstrapped confidence interval remaining slightly above zero, $ab = 0.02$, $BC_{y}$ CI [0.00, 0.05]. This was confirmed by the conservative Sobel test for indirect effects, which also showed a significant mediator effect for this psychological state, ($z = 2.04$, $p<0.05$).
4. Discussion

As hypothesised, several aspects of mental wellbeing mediated associations between ethnicity and doctor-patient interactions, including the frequency of PCP-related communication. The findings extend previous work on intercultural doctor-patient liaisons, which hitherto largely focused on negative mindsets, and did not specifically examine PCP-related contact (Paternotte et al. 2015). Ethnicity wasn’t directly related to doctor-patient communication. The discrepancy may be attributable to methodological differences. Previous studies focused on narrowly defined ‘patient’ groups (Burt et al. 2016), whereas the present study involved the general public. Since the public don’t engage as frequently with health professionals, compared to hospitalised ‘patients’ for example (Ahmed et al. 2015), ethnicity may play a more distal (i.e., indirect) role in PCP-related communication. By contrast, cultural frustrations may surface once ‘patients’ begin to engage health professionals with higher regularity and/or for longer duration (Paternotte et al. 2015). Ethnic based vexations (e.g., language barriers) then impede PCP-related decisions, for example regarding treatment or goal-setting (Paternotte et al. 2015). In this context, ethnicity may directly predict doctor-patient relations. However, as most British residents (almost 90%) have seen their doctor within the past year (IPSOS MORI 2015), the exact point at which ethnicity becomes salient is arguable, and requires further research.

South Asians were more likely to feel energetic. This disposition may partially explain the poorer doctor-patient communication amongst South Asians reported in the literature (Patel et al. 2015, Ahmed et al. 2015). If one feels lively, there is less motivation to contact a doctor to discuss a PCP (even if it is necessary to do so, due to an underlying medical condition, or substance abuse problem for example), notwithstanding various other cultural and religious disincentives (Paternotte et al. 2015). This seems to contradict the notion that positive-minded patients interact more readily with health professionals (Gallan et al. 2013).
However, perceived energy levels may transcend individual mental wellbeing, perhaps echoing the nuclear versus extended family structures dominant in Caucasian and South Asian communities, respectively (Owen 2006). Extended family members often live in close proximity (Goodley, Runswick-Cole, and Mahmoud 2013). Thus, they can support one another, both emotionally and financially, such that individual members generally feel less fatigued (e.g., Cousins or grandparents assisting with child care). However, these conditions may be confounded by other cultural or religious factors. For example, many UK South Asians are of Muslim faith, and hence partake in fasting (abstention from food and fluid intake for one month during daylight hours) (Maughan, Fallah, and Coyle 2010). Dietary intake shifts from daytime to the hours of darkness, disrupting normal sleep patterns, and potentially creating a sense of fatigue (Maughan, Fallah, and Coyle 2010). Thus, South Asians may experience more fatigue at certain times of the year (Ramadan), albeit with negligible impact on service use (Patel et al. 2015).

People who feel positive build better psychological resilience, and cope better with life’s challenges (Fredrickson 1998, 2001). They are less likely to fall sick and hence visit a doctor (Salovey et al. 2000). Indeed, the present data revealed inverse associations between a positive mindset and doctor-patient contact. However, this can be problematic for ethnic communities experiencing a surplus risk for chronic diseases or substance abuse problems that require PCPs and close monitoring. For example, South Asians felt more energetic, and respondents who felt this way were less likely to have contacted a doctor recently. Given the surplus diabetes risk in the South Asian community (Tillin et al. 2013) and the importance of PCPs in diabetes management (Diabetes UK 2009), any mindset that discourages interaction with health professionals is undesirable (Patel et al. 2015).

The most significant (and curious) finding of this report is that feeling energetic continued to mediate the effect of ethnicity on doctor-patient contact, despite controlling for
health status. General fatigue has been a common patient complaint in clinical consultations, and may reflect psychological and/or physiological processes (Berrios 1990). Feeling energetic (i.e., absence of fatigue) now appears to denote important ethnic undertones that transcend illness considerations and, more importantly, have rarely been highlighted in the literature on intercultural doctor-patient liaisons (Paternotte et al. 2015). It is possible South Asians may contact health professionals less often than Caucasians partly due to greater perceived vigour, irrespective of medical status. If so, this can be dangerous for individuals suffering medical or behavioural problems (including undiagnosed conditions) that require close monitoring via PCPs (Diabetes UK 2009). Further research is needed to understand the underlying cultural factors.

4.1 Limitations

This study has several limitations. Firstly, the outcome measures emphasised frequency of contact between doctor and patient (e.g., whether respondents had spoken with a doctor with the past fortnight/year), rather than the quality of experience (e.g., how satisfied patients felt about their most recent PCP consultation) (Wolf et al. 2014). While agreeing to a PCP may denote a productive doctor-patient liaison, there is no way to know from the present data how satisfied patients felt about their experiences with the health service (e.g., equal involved in the decision making process). Secondly, other key intercultural dimensions from the doctor-patient literature weren’t captured (e.g., communication with a patient’s relatives, or language barriers) (Paternotte et al. 2015). Additionally, while some demographic factors (age and gender) were treated covariates, the analysis made no adjustments for socio-economic status. However, socio-economic standing hasn’t emerged as a particularly salient theme in previous research on intercultural doctor-patient communication (Paternotte et al. 2015), or care planning (Coulter et al. 2015). Fourthly, the absence of a direct effect of ethnicity on doctor-
patient outcomes (i.e., path c) seems to violate the ‘Joint Significance’ approach to mediation (Baron and Kenny 1986). However, as mentioned before, contemporary (‘bootstrapping’) interpretations don't require a direct association between X and Y, in order to demonstrate mediation (Hayes 2009, 2013). Finally, the use of single-item measures may generate concern (Diamantopoulos et al. 2012), albeit evidence suggests they work similarly to multi-item measures with very large samples (Cheung and Lucas 2014).

4.2 Conclusions

The present findings extend existing literature in several ways. Firstly, the results show that, amongst the general public, ethnic differences in doctor-patient interactions, including the frequency of PCP-related communication, are partly elucidated by positive mental wellbeing. Secondly, these mediator effects may attenuate after controlling for health status and other covariates. However, the state of feeling energetic transcends differentials in medical condition, denoting robust cultural underpinnings that need further exploration. South Asians felt more energetic than Caucasians, a disposition that may partly explain poorer doctor-patient communication in the former community, and may have dangerous implications for patients suffering conditions (diagnosed or otherwise) that require PCPs.

Hitherto primary responsibility for improving intercultural doctor-patient liaisons, by projecting a positive psychological demeanour (e.g., showing empathy), has been assigned to doctors/nurses (Paternotte et al. 2015). This has been particularly so regarding South Asian patients, who may be reluctant to engage with health professionals (Patel et al. 2015), and hence have fewer opportunities to set up and/or review a PCP. The present study shifts the focus back to the patients. Given the surplus diabetes risk in South Asians, it is essential that websites, organisations, and professionals that provide this community with health information highlight the importance of PCPS, and recommend engaging regularly with
health providers, despite perceived vigour that may suggest good health. It is also important for health providers to consider how mental wellbeing in patients can be used to improve doctor-patient contact, and their capacity to discuss and agree to a care plan. As mental wellbeing seems relatively deficient in Caucasians, this ethnic group may benefit the most from any educational or training initiatives designed to augment favourable psychological dispositions.
