1 *Abstract:* The relationship between the development of social complexity in the Iberian  
2 Peninsula during the 4<sup>th</sup> and 3<sup>rd</sup> millennia BCE (Late Neolithic and Copper Age) and  
3 population movement has been a longstanding question. Biological affinity analyses were  
4 used to explore Iberian demographic dynamics, and specifically, to discern whether there is  
5 evidence for migration and gene flow between northwest African, eastern Mediterranean, and  
6 Iberian populations. Affinities based on comparisons of nonmetric traits from the Arizona  
7 State University Dental Anthropology System were estimated among samples of burial  
8 populations from three key Late Neolithic-Copper Age sites in the Portuguese Estremadura:  
9 Cova da Moura (3700-2300 BCE), Bolores (2800-2600 BCE), and Pai Mogo I (2800-2600  
10 BCE). Results indicate: 1) the possibility of genetic exchange with African and other  
11 Mediterranean peoples, 2) some measure of population continuity over time in the  
12 Estremadura, and 3) possible local isolation of populations, given distinctive patterning at the  
13 site of Pai Mogo, located 23 km north of Cova da Moura and Bolores.  
14

## 1.1 Introduction

Understanding the relationship between social complexity and demographic dynamics is a central theme in several of the grand challenges recently identified for archaeology, especially those related to movement, mobility, and migration (Kintigh et al., 2014). In the Iberian Peninsula, the emergence of social complexity developed in the 4<sup>th</sup> and 3<sup>rd</sup> millennia BCE – in the periods known as the Late Neolithic and Copper Age. During this time a number of fortified or ditched enclosure sites emerged as important social, political, and ritual centers, particularly in the fertile Guadiana and Guadalquivir river valleys of southern Iberia. Some sites extended over large areas, such as Valencina de la Concepción (Sevilla) (450 ha) (Costa et al., 2010), Marroquíes Bajos (Jaén) (113 ha) (Zafra et al., 1999), and La Pijotilla (Badajoz) (80 ha) in Spain (Hurtado, 1997), and Porto Torrão (Beja) (70 ha) (Valera and Filipe, 2004), Alcalar (20 ha) (Morán and Parreira, 2003) and Perdigões (Reguengos de Monsaraz) (>16 ha) (Valera et al., 2014) in Portugal. A diversity of tomb architecture was utilized, including megaliths, rockshelters, natural caves, hypogea, pits, and tholos (Boaventura, 2009; Boaventura et al., 2014; Silva, 2002, 2003). The manufacture of technically complex objects and personal adornments, some made from exotic raw materials such as ivory, amber, copper, gold, variscite, and rock crystal (Morgado Rodríguez et al., 2015; Müller et al., 2007; Murillo-Barroso and Martín-Torres, 2012; Murillo-Barroso et al., 2015; Odriozola et al., 2016; Schuhmacher et al., 2009; Sousa and Gonçalves, 2012; Thomas, 2011; Villalobos García and Odriozola, 2016; Valera et al., 2015), also attests to the formation of new identities and categories of social beings.

The relationship between the process of social differentiation during the 4<sup>th</sup> and 3<sup>rd</sup> millennia and population movement has been a longstanding question in Iberian archaeology. The Orientalist explanatory model was adopted by the main Iberian archeologists of the late 19<sup>th</sup> and early 20<sup>th</sup> centuries, especially in the Spanish Southeast and Portuguese Estremadura.

1 Since the pioneering studies of Siret (1913), and later work of Martin Almagro and A.  
2 Arribas at Los Millares, Afonso do Paço at Vila Nova de São Pedro, and E. Sangmeister and  
3 H. Schubart at Zambujal (Sangmeister and Schubart, 1981), the fortifications were associated  
4 with eastern Mediterranean colonists; the latter purportedly came to Iberia in search of metals  
5 and to establish outposts during the Iberian Copper Age (Siret, 1913). However, when  
6 archaeologists began applying radiocarbon dating in the 1970s, they increasingly recognized  
7 that material practices, such as megalith-building, predated their supposed exogenous models  
8 (Chapman, 1990). As a result, they turned to local social or economic factors to account for  
9 the changes between the 4<sup>th</sup> and 2<sup>nd</sup> millennia cal. BCE, and discredited “migrationism” and  
10 “diffusionism” as explanatory vehicles. Instead, they replaced their models with a “radical  
11 autochthonism” (Aranda Jimenez et al., 2015: 55). Demography took a back seat to economic  
12 and political dynamics (Gonçalves et al., 2013).

13 Through the development of analytical technologies to source raw materials and track  
14 the mobility of people, as well as new archaeological discoveries, the “Other” – both in the  
15 form of exotic materials and non-local individuals – is once again making its appearance in  
16 narratives of late prehistoric Iberian social history. For example, archaeologists had  
17 understood that ivory objects found in Copper and Bronze Age contexts pointed to long-  
18 distance exchange networks, presumably originating from sources (e.g., elephants,  
19 hippopotami) in North Africa and Egypt (Harrison and Gilman, 1977). However, recent  
20 studies by Schumacher et al. (2009) suggest the exchange was larger in scale than imagined;  
21 ivory from Asian elephants was sometimes used, as well as that from Pleistocene and African  
22 elephants. Furthermore, building on the work of Bosch Gimpera (1932) and Martínez Santa-  
23 Ollala (1941), Manen et al. (2007) submit that African exchange extended as far back as the  
24 Early Neolithic (i.e., 6<sup>th</sup> to 5<sup>th</sup> millennia BCE). Given their geographic proximity, could  
25 genetic exchange have also occurred between the human populations of Iberia and northwest

1 Africa, i.e., in the form of south-to-north gene flow and/or migration? And is there yet merit  
2 in the idea of eastern Mediterranean influence (Siret, 1913) that corresponds with the Iberian  
3 Late Neolithic-Copper Age?

4 To explore the viability of these possible scenarios based on archaeological evidence,  
5 we turned to the subfield of bioarchaeology. Specifically, we use biological affinity analyses  
6 to better understand the demographic dynamics of the time. Previous affinity studies of early  
7 Iberian populations focused on periods that, like across much of Europe, ushered in  
8 significant social and economic change, i.e., the Mesolithic-Neolithic (c. 5600 BCE) (e.g.,  
9 Jackes et al., 2001) and Middle-Late Neolithic transitions (4<sup>th</sup>-3<sup>rd</sup> millennia BCE  
10 (Boaventura, 2009; Boaventura et al., 2014; Horwath et al., 2014). A primary goal of these  
11 studies was to assess whether the change was accompanied by population replacement or,  
12 minimally, discernable outside genetic input. Our research continues this diachronic  
13 emphasis.

14 Biological affinities based on comparisons of nonmetric traits from the Arizona State  
15 University Dental Anthropology System (Turner et al., 1991) were estimated among samples  
16 of burial populations from three key Late Neolithic-Copper Age sites in Portugal: Cova da  
17 Moura (3700-2300 BCE), Bolores (2800-2600 BCE), and Pai Mogo I (3000-2600 BCE).  
18 Dental trait data are ideal for this investigation because, like all local burial sites of this  
19 period, the remains are so fragmented and commingled that most skeletal elements can  
20 neither be measured (e.g., for craniometrics, geometric morphometric study, etc.) nor  
21 recombined into individuals. The three samples come from the Estremadura of west-central  
22 Portugal (Fig. 1), an important region for understanding biological diversity given its many  
23 mortuary sites and favorable conditions for skeletal preservation (Boaventura et al., 2014;  
24 Silva, 2002). They, in turn, were compared to four extra-regional samples affiliated with  
25 northwest Africa and three from the eastern Mediterranean to address the two questions

1 posed above. If gene flow and/or immigration from either region did occur – in potential  
2 correspondence with the 4<sup>th</sup>-3<sup>rd</sup> millennia increase in social differentiation – it may be evident  
3 in the Portuguese samples.

4 **[FIGURE 1 HERE]**

5 At a basic level, the African scenario may be tested statistically by phrasing it in the  
6 form of a null hypothesis, viz.: there is no significant difference between one or more  
7 samples from the Portuguese Estremadura and northwest Africa. By substituting the latter  
8 region, a second null hypothesis can be created to test for any Mediterranean input. For both,  
9 the mean measure of divergence distance statistic (Irish, 2010; Sjøvold, 1977) was applied to  
10 compare the dental data among samples. If one or both of these hypotheses cannot be  
11 rejected, discernable extra-regional genetic input may have occurred. Of course, such  
12 complex problems are unlikely to be resolved through simply reaching or failing to reach an  
13 arbitrary alpha level; however, by considering the weight of evidence across all inter-sample  
14 comparisons, along with the aid of supplementary quantitative and illustrative methods  
15 (below), some pertinent insights may be achieved. As usual, all results are contingent upon  
16 two assumptions (Irish 2005, 2006, 2016; Irish et al., 2014) that: 1) all samples are  
17 representative of their corresponding populations, and 2) phenetic similarity provides some  
18 indication of genetic relatedness (Larsen, 1997; Martínón-Torres et al., 2007; Rightmire,  
19 1999; Scott et al., 1983; Scott and Turner, 1997). In sum, our goal is to complement and build  
20 upon the findings of prior archaeological and bioarchaeological researchers to promote a  
21 better biocultural understanding of the ancient peoples of the Iberian Peninsula and,  
22 specifically, Portugal.

23 *1.2 Materials*

24 The three Portuguese samples are suitable for evaluating local biological/genetic variation  
25 during the Late Neolithic-Copper Age because: 1) Cova da Moura predates and temporally

1 overlaps with Bolores, while the two sites are located just 2 km apart in the Rio Sizandro  
2 valley, 2) the Bolores and Pai Mogo I sites are largely contemporary, but the latter is located  
3 two river valleys to the north, 23 km distant near the Atlantic coast, and 3) Cova da Moura  
4 and Pai Mogo I also overlap in time and are spatially distinct. Dietary differences and  
5 differential, albeit low-level immigration based on stable isotopes have also been reported  
6 (Guiry et al., 2016; Waterman et al., 2014, 2015). All samples were studied as part of a  
7 broader analysis of social change in the Sizandro/ Alcabrichel river valleys between the 4<sup>th</sup>-  
8 2<sup>nd</sup> millennia BCE, codirected by the second author and Michael Kunst (Lillios 2015,  
9 Waterman et al., 2016).

10 Cova da Moura is a natural cave site in the Sizandro river valley. It was discovered in  
11 1930, with preliminary excavations undertaken in 1932 (Belo et al., 1961). Subsequent  
12 fieldwork was conducted in 1961 by Belo and Trindade (Gallay and Spindler, 1970; Spindler,  
13 1981). Seven radiocarbon dates were obtained on the human remains, which indicate that the  
14 site was used between 3700 and 2300 BCE. Based on duplicate skeletal elements the MNI is  
15 90 individuals, including 15 sub-adults (Silva, 2002, 2003). However, as noted, all remains  
16 are fragmented and comingled, so multiple maxillae, mandibles, and loose teeth were  
17 combined to yield “composite” individuals for analyses following standard procedure (Irish,  
18 1998a). Thus, the Cova da Moura dental sample consists of 41 such individuals. In terms of  
19 material culture, Cova da Moura is by far the richest burial site in the region. Grave goods  
20 include limestone and bone idols, green stone pendants, gold artifacts, engraved slate plaques,  
21 bone, ivory, and variscite rabbit figurines, beads, and pre-Beaker and Beaker ceramics (Belo  
22 et al., 1961; Gallay and Spindler, 1970; Spindler, 1981; Thomas, 2011).

23 Bolores is a semi-artificial cave located in the Sizandro river valley, about 15 km  
24 from the Atlantic coast. Following testing in 1986, four seasons of excavation were  
25 conducted by the second author and a team from the University of Iowa (Lillios et al., 2015).

1 The site itself is about 3 x 5 m, subdivided by large stone blocks into three chambers.  
2 Approximately 75% of the site was excavated. The MNI is 36, which includes adults,  
3 adolescents, and children. Of these, 36 individual dentitions could be identified for analysis.  
4 Eleven AMS dates were obtained that put the use of the site between 2800-2600 BCE, with a  
5 short period of use near 1800 BCE. Material culture is relatively scarce, and consists of stone  
6 and shell beads, stone 'idols' of various forms, flint blades, and ceramic vessels.

7         Pai Mogo I (or Paimogo I) is a corbel-vaulted tomb on the Rio Grande, 1 km from the  
8 Atlantic coast. The site was first discovered in 1968, with excavations carried out in 1971.  
9 Four dates on human remains from the site indicate the site was in use from 3000 to 2600  
10 BCE (Silva, 2002). Little information is available about the context of the human remains  
11 recovered from this burial (Gallay et al., 1973). The MNI is 413 (Silva 2002, 2003). Forty-  
12 nine composite dentitions were assembled for analysis. An extensive array of Late Neolithic  
13 and Copper Age artifacts was found, including decorated pre-Beaker and Beaker ceramics,  
14 groundstone and flaked stone tools, bone tools, limestone idols, other limestone objects, and  
15 copper implements (see Spindler and Gallay, 1973; Gallay et al., 1973).

16         Lastly, to assess potential outside genetic influence, the above were compared with  
17 seven extra-regional samples. Four are linked with northwestern Africa, i.e., Neolithic  
18 Capsian (n=24), precontact Canary Islanders (n=163), historic Kabyle (n=32) Berbers, and a  
19 fourth sample from an area once inhabited by Shawia Berbers (n=26). The remaining three  
20 samples derive from countries along the north shore of the Mediterranean: 1) Italy, which  
21 consists of 90 Roman and historic individuals, 2) Greece (n=77 individuals), dating from  
22 Classic and historic times, and 3) Turkey (n=40) that, along with individuals from nearby  
23 Cyprus, dates from Classic (Anatolian) to Ottoman times (Fig. 2). Although heterogeneous in  
24 composition, particularly the latter sample, they should at least yield some measure of  
25 characterization of eastern Mediterranean populations (re: Siret, 1913). All comparative

1 samples, like the Portuguese, were recorded by the first author; thus, inter-observer error is  
2 not a concern and any intra-observer recording variation was found to be minimum and  
3 random. Background information has been presented elsewhere (Horwath 2012; Horwath et  
4 al., 2014; Irish, 1993, 1998b, 1998c, 2000). For quick reference, summary data for all 10  
5 samples (n=578 total individuals) are listed in Table 1.

6 **[FIGURE 2 HERE]**

7 **[TABLE 1 HERE]**

### 8 *1.3 Methods*

#### 9 *1.3.1 Dental trait recording*

10 Up to 125 nonmetric crown, root, and osseous oral traits were recorded in each dentition. For  
11 those with bilateral expression, both antimeres were recorded and, allowing for asymmetry,  
12 the side with the greatest expression was counted (Turner and Scott, 1977); the aim is to  
13 identify each trait's maximum genetic potential for each individual (Turner, 1985; Turner et  
14 al., 1991). Thirty-six of these traits (see list in Table 2) used by the first author in earlier  
15 dental studies (e.g., Irish, 1993, 1997, 2005, 2006, etc.) were recorded for the following  
16 analyses. Except for UI1 midline diastema (Irish, 1993), all are part of the Arizona State  
17 University Dental Anthropology System (ASUDAS); the traits are recorded with the aid of  
18 23 rank-scale reference plaques that help standardize scoring by providing representations of  
19 minimum, maximum, and intermediate expressions (Scott and Turner, 1997; Turner et al.,  
20 1991). The ASUDAS traits have a range of advantages (Irish, 1993, 1998b, 1998c 2005,  
21 2006), but in brief they: 1) can be recorded despite slight attrition (though see below) or are  
22 unaffected by it in the cases of root and osseous traits, 2) have nominal inter- and intra-  
23 observer error rates when recording (as above), 3) are easy to identify, and 4) represent all  
24 dental morphogenetic fields. Of greater importance, the traits have a high genetic component  
25 in expression (Larsen, 1997; Martín-Torres et al., 2007; Rightmire, 1999; Scott, 1973;

1 Scott and Turner, 1997), and they are evolutionarily conservative, making them excellent  
2 markers for biodistance analyses (Larsen, 1997). Another advantage is an overall lack of  
3 sexual dimorphism (Bermúdez de Castro, 1989; Hanihara, 1992; Irish, 1993; Scott, 1973,  
4 1980; Smith and Shegev, 1988), to permit the pooling of sexes for maximizing sample size. A  
5 complete description of the ASUDAS is presented in Turner et al. (1991) and Scott and  
6 Turner (1997).

### 7 *1.3.2 Quantitative analyses*

8 All rank-scale ASUDAS traits were first dichotomized into categories of present or absent,  
9 based on their appraised morphological thresholds (Nichol, 1990; Scott, 1973) according to  
10 standard procedure (Irish, 1993; Turner, 1985, 1987). Dichotomization simplifies the  
11 tabulation of trait frequencies for presentation, and is necessary before these data can be  
12 compared with most distance statistics, including the mean measure of divergence (MMD) as  
13 used here (Berry and Berry, 1967; Green and Suchey, 1976; Harris and Sjøvold, 2004; Irish,  
14 2010; Sjøvold, 1973, 1977). However, relative to prior studies (Irish, 1993, 1997, 2005, 2006,  
15 etc.) breakpoints that define “presence” were shifted upward for two important traits: UM1  
16 Carabelli’s (by 3 grades to describe cusp expression only) and LP2 lingual cusp (1 grade, to  
17 better discern cusp number). This strategy minimizes the potential for grade shift and  
18 sampling biases when scoring traits in the present samples, which exhibit marked attrition  
19 differences among geographic regions; it also helps to maintain all-important sample size  
20 (Burnett et al., 2013; Burnett, 2016).

21 Next, the MMD was used to estimate among-sample phenetic affinities by calculating  
22 a measure of dissimilarity between each sample pair, i.e., high values indicate divergence and  
23 vice versa. Beyond holding several advantages over other distance measures (Irish, 2010) the  
24 MMD works with pooled sample data, to better address missing data in archaeological  
25 remains and the use of composite individuals. However, it is important to thoroughly edit

1 these data. Traits with little or no contributory information should be deleted (Harris and  
2 Sjøvold, 2004). Those which are invariant can be recognized qualitatively, whereas traits that  
3 are the least, or conversely most, likely to drive inter-sample variation may be quantitatively  
4 identified, e.g., with correspondence analysis (Irish, 2005, 2006) or, like in the present study,  
5 principal components analysis (PCA) (Irish, 2016; Irish and Guatelli-Steinberg, 2003). The  
6 MMD distances should also be based on as many traits as possible, although none should be  
7 highly inter-correlated – which could render the results inaccurate (Sjøvold, 1977). To  
8 identify such traits the rank-scale data were submitted to Kendall's tau-*b* correlation  
9 coefficient.

10         The MMD formula contains the Freeman and Tukey angular transformation to correct  
11 for low ( $\leq .05$ ) or high ( $\geq .95$ ) trait frequencies and small sample sizes ( $n \geq 10$ ) (Green and  
12 Suchey, 1976; Sjøvold, 1973, 1977). To determine if two samples differ significantly, the  
13 MMD value is compared with its standard deviation (SD). If the  $MMD > 2 \times SD$ , the null  
14 hypothesis of  $P_1 = P_2$  (where  $P$  = sample population) is rejected at the 0.025 level. The  
15 MMD and standard deviation formulae, rationale for assessing significance, and other  
16 information can be accessed elsewhere (Irish, 2010; Sjøvold, 1977). Beyond presenting an  
17 MMD distance matrix, interval-level multi-dimensional scaling (MDS) (Kruskal and Wish,  
18 1978) in SPSS 23.0 Procedure Alscal was used to create 3D spatial representations of the  
19 sample variation to aid interpretation.

20         Finally, the correlation between MMD and geographic distances in km was  
21 calculated with a two-tailed Mantel test (Smouse et al., 1986), and both distances were used  
22 as coordinates to plot pertinent sample pair relationships in 2D. These methods help explore  
23 if any Portuguese samples appear more similar to an extra-regional group than expected,  
24 under the assumption that genetic (and phenetic) relatedness among populations decreases  
25 exponentially as spatial distance increases (Relethford, 2004). Gene flow, the causative agent

1 with isolation-by-distance (Wright, 1943), cannot pertain directly to the present diachronic  
2 samples; nevertheless, some indication of potential African or Mediterranean influence may  
3 be obtained to supplement the MMD results. The Geographic Distance Matrix Generator  
4 (vers. 1.2.3) (Ersts, 2014) was employed to calculate inter-sample straight line distances. The  
5 latter do not reflect reality on the landscape; however, because all comparative sample  
6 locations (especially eastern Mediterranean) are approximations, as would be potential  
7 migration routes toward Iberia, linear distances (though underestimates) should be less  
8 biased for analytical purposes.

#### 9 *1.4 Results*

10 Percents of individuals that express each trait and the total number scored are listed in Table  
11 2. The ASUDAS present/absent dichotomies are provided under each trait name. Samples  
12 with <10 trait observations adversely impact several traits, especially CAP (see table and  
13 figure captions for the key to three-letter abbreviations). The BOL and PAI samples are  
14 affected similarly for palatine torus, midline diastema, and rocker jaw. Such data are unlikely  
15 to be characteristic of the parent populations; results using them should be interpreted with  
16 caution and/or they should be addressed during the trait editing process.

#### 17 **[TABLE 2 HERE]**

18 That said, the MMD is a very robust statistic, so to obtain a preliminary indication of  
19 affinities among samples all 36 traits were first compared. The distance matrix is presented in  
20 Table 3, and the MDS solution from it (Fig. 3) provides a good representation, where the  $r^2$   
21 value is 0.897 and Kruskal's stress formula 1 is 0.113; for the latter value <0.10 is considered  
22 excellent and  $\geq 0.15$  unacceptable (Borgatti, 1997). Many significant MMD distances  
23 ( $p \leq 0.025$ ) reflect the trait variation evident across samples (Table 2) including, among others,  
24 interruption groove UI1 [range of 0-46% (or 60% in the small CAP sample)], distal accessory  
25 ridge UC (8-74 %), rocker jaw (0-30%), and torsomolar angle LM3 (0-31%). However, the

1 loose association of samples by geographic region in the figure (CDM/BOL/PAI,  
2 GRK/ITY/TRK, and CAN/CAP/KAB/SHA) is indicative of relative among-sample trait  
3 uniformity from those regions (again see Table 2).

4 **[TABLE 3 and FIGURE 3 HERE]**

5 Trait editing was then conducted as noted above. Non-contributory traits odontome  
6 P1-P2 (0-3% across samples), midline diastema (0-5%), mandibular torus (0-4%), and  
7 protostylid LM1 (0%) were removed. Percent data in the remaining 32 traits were submitted  
8 to PCA to identify less evident non-contributors in nine of the 10 total samples; CAP was not  
9 included after judging that many of its small and likely non-representative trait frequencies  
10 artificially increased several resulting loadings.

11 Eight components (eigenvalues >1.0) account for 100% of the total variance, though  
12 the PCA scree plot (not shown) indicates that the first three (58% variance) are most  
13 important; their un-rotated loadings are provided in Table 4. Those traits having very strong  
14 positive or negative loadings (i.e., >|0.5|) drive most of the variation as depicted in a graph of  
15 the group component scores in Figure 4. For Comp 1, loadings between 0.555 and 0.891 for  
16 tuberculum dentale UI2, distal accessory ridge UC, cusp 5 UM1, enamel extension UM1,  
17 root number UM2, anterior fovea LM1, deflecting wrinkle LM1, and cusp 7 LM1 push  
18 samples with high percents of these traits nearer the positive end of the x-axis (BOL, PAI,  
19 and to a lesser extent, CDM and ITY). Negative loadings of -0.589 to -0.855 for interruption  
20 groove UI2, congenital absence UM3, rocker jaw, cusp number LM2, and torsomolar angle  
21 LM3 typify samples toward the x-axis' opposite end (e.g., TRK, GRK, SHA). Traits of  
22 greater importance are also evident on the y- (Comp 2) and z-axes (Comp 3). As such,  
23 palatine torus, shoveling UI1, double shoveling UI1, hypocone UM2, and lingual cusp LP2  
24 (loadings <|0.5| on all axes) were dropped because they are mostly noncontributory. Varimax

1 rotation, which maximizes differences between large and small loadings, provided similar  
2 results (not shown).

3 Kendall's tau-*b* correlations among the remaining traits revealed high values ( $>|0.5|$ )  
4 for molar cusp number LM1 with: molar cusp number LM2, deflecting wrinkle LM1, and  
5 cusp 7 LM1 ( $\tau_b = 0.573, 0.670, \text{ and } 0.818$ , respectively). Similarly high values were found  
6 between c1-c2 crest LM1 and anterior fovea LM1 and, again, deflecting wrinkle LM1 with  
7 cusp 7 LM1 ( $\tau_b = 0.657, 0.787, \text{ and } 0.706$ ). Therefore, together with lower loadings than other  
8 non-correlated traits (Table 4), molar cusp number LM1 and mandibular torus were dropped.  
9 As a result 25 traits, as denoted by asterisks, in Table 4 were used in the final MMD  
10 comparison.

11 **[TABLE 4 and FIGURE 4 HERE]**

12 This MMD distance matrix is presented in Table 5. Heterogeneity is again evident by  
13 the number of significantly different MMD distances. However, with a focus on the three  
14 Portuguese samples, the greater emphasis on divergence after deleting invariant and other  
15 traits that are non-contributory served to make CDM, BOL, and PAI, more distinct – from the  
16 other samples and one another (i.e., note the increase in MMD distances). The MDS solution  
17 again provides a good representation of the matrix, with the  $r^2$  and Kruskal's stress formula 1  
18 values improving to 0.919 and 0.109, respectively. Greater separation among the Portuguese  
19 samples is evident, though the new configuration (Fig. 5) otherwise looks similar in  
20 patterning to the 36-trait MDS graph (Fig. 3) in the association of samples by geographic  
21 region. To quantify this apparent correspondence, the 25-trait MMD distances were  
22 compared to geographic distances among sites and/or regions (Table 6); the Mantel  
23 correlation between matrices,  $r=0.247$  ( $p=0.102$ ), is positive though weak (per Cohen, 1988).

24 **[TABLES 5-6 and FIGURE 5 HERE]**

1           Lastly, CDM, BOL, and PAI were plotted individually with the rest of the samples  
2 using pairwise geographic and MMD distances as coordinates on the x- and y-axes in Figures  
3 6-8. In each plot, a linear equation reference line (solid black) with a slope (b) of 1 and y-  
4 intercept (a) of 0 is provided (i.e.,  $y = 0 + 1x$ , where  $y = a + bx$ ) to simply illustrate where the  
5 other Portuguese and extra-regional samples would be located if a 1:1 correspondence existed  
6 between spatial and phenetic distances. The real sample locations identify those which are  
7 phenetically closer to the respective Portuguese sample than expected (i.e., below reference  
8 line), and vice versa (above line), relative to geographic separation. By way of comparison,  
9 the actual regression coefficient is also provided as the line of best fit (dashed) through the  
10 data cloud in each figure. Assuming that phenetic affinity is a function of spatial separation  
11 (as above), coefficients of determination were calculated via the linear regression procedure  
12 in SPSS 23.0 for CDM ( $r^2=0.095$ ,  $r=0.308$ ,  $p=0.420$ ), BOL ( $r^2=0.290$ ,  $r=0.539$ ,  $p=0.135$ ), and  
13 PAI ( $r^2=0.764$ ,  $r=0.874$ ,  $p=0.002$ ). Thus for CDM, 9.5% of the variability in MMD distances  
14 is associated with, or explained by, variability in the geographic distances. The corresponding  
15 values for BOL and PAI are 29.0% and 76.4%.

16 **[FIGURES 6-8 HERE]**

### 17 *1.5 Discussion*

18 Our overarching goal in this analysis was to ascertain if there is evidence of genetic input  
19 from northwestern African and/or eastern Mediterranean populations in late prehistoric  
20 peoples of the Portuguese Estremadura. Several high-frequency African traits (Irish, 1993,  
21 1997, 1998a, 1998b, 1998c) are present in CDM, BOL, and/or PAI, including: UI1 labial  
22 curvature, Bushman canine UC, and LM1 cusp 7 (Table 2; also Table 4 loadings). In  
23 accordance, the 36- and, particularly, 25-trait MMD distances (Tables 3 and 5) and MDS  
24 scatterplots (Figs. 3 and 5; also see Fig. 4 PCA plot) indicate that the KAB and, to a lesser  
25 extent, SHA Berber samples, share very low and mostly insignificant phenetic distances with

1 CDM and BOL (25-trait MMD between 0.002 and 0.070), though not with PAI (0.125-  
2 0.128). As mentioned, archaeological evidence of African-sourced raw materials and artifacts  
3 is documented in southern Iberia (Harrison and Gilman, 1977; Manen et al., 2007), including  
4 ivory from North Africa at the site of Zambujal, a Copper Age settlement just 2 km south of  
5 Cova da Moura and Bolores (Sangmeister and Schubart, 1981). Perhaps an African  
6 contribution to the Estremadura gene pool did take place. However, ubiquitous traits in  
7 eastern Mediterranean populations, like UM2 hypocone reduction (grades <3) and two-rooted  
8 LC (Scott and Turner, 1997), also occur in the Portuguese. The same MMD matrices and  
9 inter-sample plots identify a west-east affinity, most notably BOL (25-trait MMD=0.031)  
10 and, to a lesser degree, CDM (0.043) with ITY. The PAI sample (0.108), from farther north  
11 in the Estremadura, is again an exception (discussed below). Imported artifacts and materials  
12 from the east are also known (Schumacher et al., 2009). So genetic exchange with eastern  
13 Mediterranean peoples may too have occurred.

14         Of course, these extra-regional dental similarities may simply be a function of  
15 Portugal's proximity to northwest Africa and Italy relative to more geographically divergent  
16 samples (per Relethford, 2004; Wright, 1943), as in describing a vast, circum-Mediterranean  
17 cline; a positive though weak correlation does exist between the MMD and geographic  
18 straight-line distances. On the other hand the resemblance of CDM and BOL to KAB, SHA,  
19 and ITY may be indicative of direct contact (à la Siret, 1913), as in actual migration and/or  
20 gene flow into southern Iberia and, specifically, the Estremadura. Based on isotopic evidence,  
21 Waterman et al. (2014) did find that four of 12 skeletons sampled at CDM were non-local. In  
22 support of external influence, only 9.5% of the variability in MMD distances for CDM and  
23 29% for BOL, as noted, is associated with the variability in geographic distances with the  
24 remaining samples. These results imply that at least some of the latter are not plotted where  
25 they "should" be (Figs. 6-7), assuming phenetic affinity is directly related to spatial

1 separation. Focusing only on extra-regional comparisons, CAP and, to a lesser extent, CAN  
2 are plotted above the solid black reference line, meaning they are more divergent phenetically  
3 from CDM than anticipated based on geographic location. Below this line the opposite is true  
4 for KAB and ITY, which share low MMD distances with CDM (Table 5), and SHA, GRK,  
5 and TRK, which differ significantly from this Portuguese sample. With some variation, inter-  
6 sample patterning for BOL is similar (Fig. 7). Therefore, based on the weight of the evidence,  
7 namely: 1) extra-regional traits in the Portuguese, 2) pertinent low and insignificant MMD  
8 distances, and 3) closer-than-expected plots of KAB and ITY, among others, neither of the  
9 hypotheses in the introduction can be rejected – though with qualification. Specifically, there  
10 is no significant difference between one or more samples from the south-central Portuguese  
11 Estremadura (CDM and BOL) and northwest Africa (KAB and SHA), nor between CDM and  
12 BOL and the eastern Mediterranean (ITY). The PAI sample does not exhibit overt extra-  
13 regional input based on these analyses. It differs significantly from all comparative samples  
14 (Table 5), and any similarities do indeed appear to be mostly a function of geographic  
15 distance ( $r^2=0.764$ ,  $p= 0.002$ ) (Fig. 8).

16         Within the Estremadura, dental heterogeneity is evident. The average intra-region 25-  
17 trait MMD among CDM, BOL, and PAI, is 0.058 (calculated from Table 5); despite issues  
18 affecting the composition of several comparative samples (above), the corresponding value  
19 for northwest Africa (CAN, CAP, KAB, and SHA) is 0.025, whereas that for the eastern  
20 Mediterranean (ITY, GRK, and TRK) is 0.015. The phenetic similarity between CDM and  
21 BOL is suggestive of short term continuity in the Rio Sizandro valley, but the MMD of 0.036  
22 ( $p<0.025$ ) is high considering a separation of 2 km between sites (Figs. 6-7). The uniqueness  
23 of PAI is clear (Fig. 8). Though most akin to CDM (MMD=0.058) and BOL (0.079), it is  
24 significantly different ( $p>0.025$ ) from both; Pai Mogo 1 is situated 23 km north from Cova da  
25 Moura and Bolores yet, among other possible factors, this relatively small distance

1 interspersed by two river valleys was seemingly a contributor to substantial biocultural  
2 isolation. As mentioned, differences in diet, artifacts, and architecture were also reported  
3 between areas (Gallay et al., 1973; Guiry et al., 2016; Spindler and Gallay, 1973; Waterman  
4 et al., 2014, 2015). This heterogeneity, the divergence of PAI in particular (at least compared  
5 to the samples in this study), reminds us that our understanding of the Iberian Late  
6 Neolithic/Copper Age must include recognition of variation – both regional and community-  
7 wide. Inhabitants of communities at this time may have been diverse in biological origin and,  
8 likely, the experiences of their worlds. Such diversity may help identify possible tensions  
9 within society that generated profound social changes by the Early Bronze Age, c. 2200 BCE,  
10 including the abandonment of settlements and emergence of new, individualized mortuary  
11 practices.

12         Lastly, relationships among all 10 samples are instructive. The demonstrable  
13 distinction by geographic region (e.g., Figs. 3 and 5) and relative intra-region similarity  
14 (above), quantified by the Mantel correlation ( $r=0.247$ ), support the viability of these dental  
15 nonmetric analyses. In fact, when northwest African-associated CAN is dropped from study,  
16 the  $r$ -value between the 25-trait MMD and geographic distances increases substantially to  
17 0.05 ( $p=0.002$ ), a strong positive correlation (Cohen, 1988). Canary Islanders are considered  
18 by researchers to be something of an outlier. Though descendants of early (potentially  
19 Neolithic) Berbers, the remote island location led to genetic isolation in these non-seagoing  
20 peoples, with only subsequent one-way gene flow – mostly from Europeans beginning in the  
21 15<sup>th</sup> century CE (Bermúdez de Castro, 1989; Guatelli-Steinberg et al., 2001; Irish, 1993;  
22 Mercer, 1980; Schwidetsky, 1963). The low and insignificant MMD distances of CAN with  
23 both Berber samples and Neolithic CAP, plus comparable values with geographically distant  
24 but younger ITY, GRK, and TRK, though not older CDM, BOL, or PAI, are supportive of  
25 these known and suspected biological relationships. Other links between the northwest

1 African and eastern Mediterranean samples are obvious (Tables 3 and 5, Figs. 3 and 5). As  
2 well, high-frequency African traits are present to varying degrees in ITY, GRK, and TRK,  
3 and vice versa (Table 2). These findings are suggestive of more than just indirect contact  
4 among circum-Mediterranean populations, contra the strict anti-migrationism and  
5 diffusionism interpretations of some researchers.

6 In sum, our study has attempted to better understand the cultural and demographic  
7 dynamics of human communities within the Portuguese Estremadura, using three samples  
8 dated between 3700-2300 BCE. Results indicate intra-regional heterogeneity relative to  
9 samples from other Mediterranean regions, though with some measure of population  
10 continuity, particularly in the Sizandro River valley. That said, long-range genetic input from  
11 more distant, yet neighboring regions, such as northwestern Africa and the eastern  
12 Mediterranean, cannot be ruled out. These data parallel findings of human migration at Cova  
13 da Moura and elsewhere in the Late Neolithic and Copper Age, based upon isotopic analyses  
14 of human remains in collective burials (Waterman et al., 2014). This correspondence may  
15 imply that exotic materials recovered from settlement and burials of this time are indicative  
16 of down-the-line exchange but, again, actual immigration may be possible based on the  
17 present quantitative analyses. As usual, it was likely a combination of influences that led to  
18 the emergence of social complexity during the Late Neolithic/Copper Age in the 4<sup>th</sup> and 3<sup>rd</sup>  
19 millennia BCE, not mutually exclusive migrationism versus autochthonism. Whatever the  
20 case, all explanatory models should remain in play until fully discredited. Further dental  
21 nonmetric and (planned) genetic analyses of human remains in burials dating to earlier and  
22 contemporary periods in Portugal, and greater Iberia, should help to clarify these findings.

1 *Figure legends*

2 **Figure 1.** Origin locations of the three Portuguese Late Neolithic-Copper Age samples.

3  
4 **Figure 2.** Origin locations of the Portuguese and comparative samples. See Table 1 and text  
5 Section 1.2 for sample compositions.

6  
7 **Figure 3.** Three-dimensional MDS of 36-trait MMD distances among the three Portuguese  
8 and seven comparative samples. The three-letter sample abbreviations are defined in Tables  
9 1-3 and 5-6.

10  
11 **Figure 4.** Three-dimensional scatterplot of the first three components among the three  
12 Portuguese and six comparative samples (without CAP; see text) for 32 dental traits from  
13 Table 4. Accounts for 58.14% of the total variance (23.32% on x-axis, 19.47% on y-axis, and  
14 15.34% on z-axis). Sample abbreviations defined in Tables 1-3 and 5-6.

15  
16 **Figure 5.** Three-dimensional MDS of 25-trait MMD distances among the three Portuguese  
17 and seven comparative samples. The three-letter sample abbreviations are defined in Tables  
18 1-3 and 5-6.

19  
20 **Figure 6.** Two-dimensional scatterplot of the CDM sample relative to the other Portuguese  
21 and comparative samples based on geographic (x-axis) vs. phenetic (y-axis) distances. Solid  
22 black linear equation reference line with slope (b) of 1 and y-intercept (a) of 0 provided (i.e.,  
23  $y = 0 + 1x$ , where  $y = a + bx$ ) to illustrate where the other samples would be if 1:1  
24 correspondence existed between the distances. The actual regression coefficient is also  
25 provided as the line of best fit (dashed) through the data cloud in each figure (with equation  
26 provided). See text Section 1.4 for details.

27  
28 **Figure 7.** Two-dimensional scatterplot of the BOL sample relative to the other Portuguese  
29 and comparative samples based on geographic (x-axis) vs. phenetic (y-axis) distances. Solid  
30 black linear equation reference line with slope (b) of 1 and y-intercept (a) of 0 provided (i.e.,  
31  $y = 0 + 1x$ , where  $y = a + bx$ ) to illustrate where the other samples would be if 1:1  
32 correspondence existed between the distances. The actual regression coefficient is also  
33 provided as the line of best fit (dashed) through the data cloud in each figure (with equation  
34 provided). See text Section 1.4 for details.

35  
36 **Figure 8.** Two-dimensional scatterplot of the PAI sample relative to the other Portuguese and  
37 comparative samples based on geographic (x-axis) vs. phenetic (y-axis) distances. Solid black  
38 linear equation reference line with slope (b) of 1 and y-intercept (a) of 0 provided (i.e.,  $y = 0$   
39  $+ 1x$ , where  $y = a + bx$ ) to illustrate where the other samples would be if 1:1 correspondence  
40 existed between the distances. The actual regression coefficient is also provided as the line of  
41 best fit (dashed) through the data cloud in each figure (with equation provided). See text  
42 Section 1.4 for details.

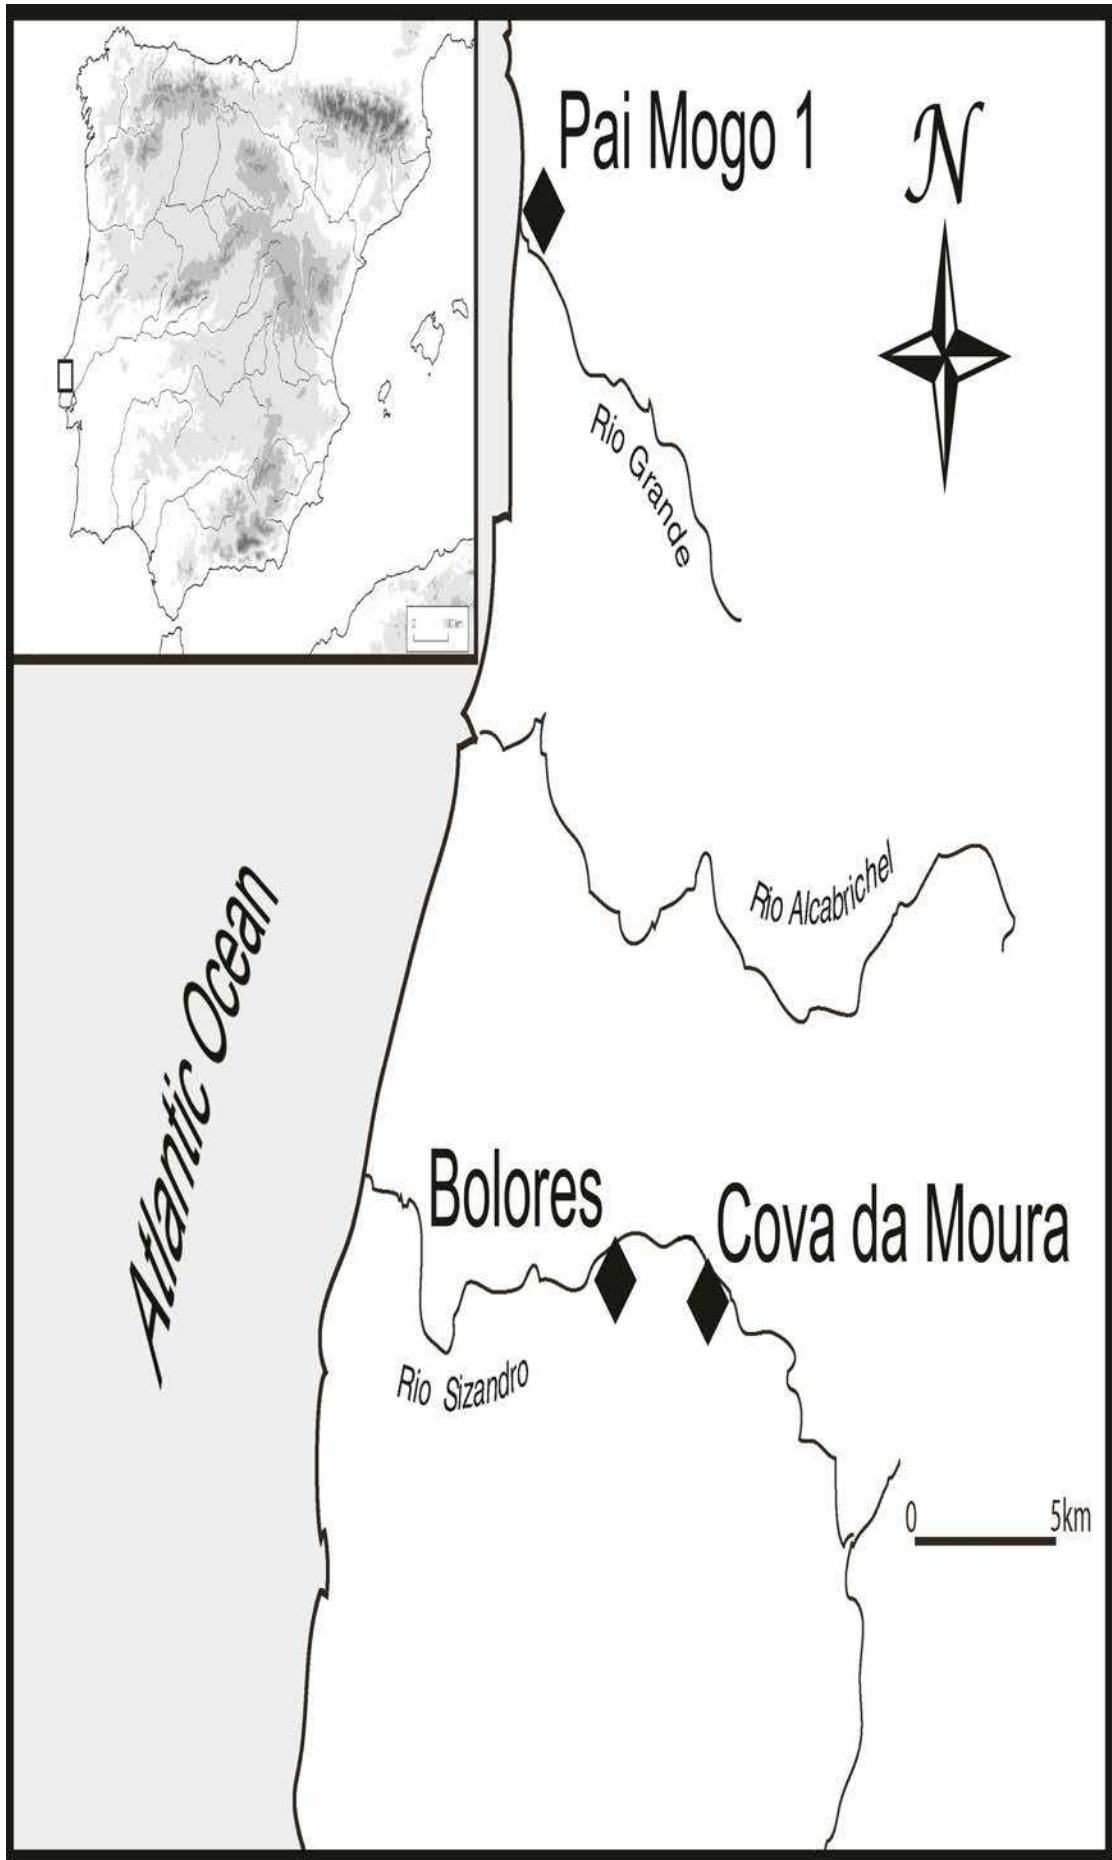

TABLE 1. The three Portuguese and seven comparative dental samples.

Sample	Geographic Origin	Affiliation	Dates	n	Institution*
<u>Portugal</u>					
Bolores (BOL)	Estremadura	Neolithic/Copper Age	2800-2600 BCE	36	MMLT
Cova da Moura (CDM)	Estremadura	Neolithic/Copper Age	3700-2300 BCE	41	MMLT
Pai Mogo I (PAI)	Estremadura	Neolithic/Copper Age	3000-2600 BCE	49	MMLT
<u>NW Africa</u>					
Canary Islanders (CAN)	Canary Islands	Precontact Guanche	400-900(?) CE	163	NMNH, MH
Capsian (CAP)	Algeria and Tunisia	Early to Middle Neolithic	6500–3000 BCE	24	UM
Kabyle (KAB)	Northern Algeria	Berber	1800–1900s CE	32	MH
Shawia (SHA)	Southern Algeria	Berber	1800–1900s CE	26	MH
<u>S Europe</u>					
Greece (GRK)	Greece	Classic to historic	475–300 BCE to historic	77	AMNH
Italy (ITY)	Italy	Roman and historic	30 BC–AD 395 to historic	90	NHM
Turkey (TRK)	Anatolia/Turkey and Cyprus	Classic to Ottoman	>300 BCE to ~14 <sup>th</sup> Cent CE	40	AMNH

\*Institutions in which the samples are curated: MMLT = Museu Municipal Leonel Trindade - Torres Vedras; NMNH = National Museum of Natural History, Washington, DC; MH = Musée de l’Homme, Paris; UM = University of Minnesota, Minneapolis; AMNH = American Museum of Natural History, New York; NHM = Natural History Museum, London.
