ABSTRACT

We report on the discovery of SN 2014J in the nearby galaxy M82. Given its proximity, it offers the best opportunity to study a thermonuclear supernova (SN) over a wide range of the electromagnetic spectrum. Optical, near-IR, and mid-IR observations on the rising light curve, orchestrated by the intermediate Palomar Transient Factory, show that SN 2014J is a spectroscopically normal Type Ia supernova (SN Ia), albeit exhibiting high-velocity features in its spectrum and heavily reddened by dust in the host galaxy. Our earliest detections start just hours after the fitted time of explosion. We use high-resolution optical spectroscopy to analyze the dense intervening material and do not detect any evolution in the resolved absorption features during the light curve rise. Similar to other highly reddened SNe Ia, a low value of total-to-selective extinction, RV ≲ 2, provides the best match to our observations. We also study pre-explosion optical and near-IR images from Hubble Space Telescope with special emphasis on the sources nearest to the SN location.

Key words: dust, extinction – galaxies: individual (Messier 82) – supernovae: individual (SN 2014J)

1. INTRODUCTION

Type Ia supernovae (SNe Ia) are among the most luminous transient events at optical wavelengths and extremely valuable tools to measure cosmological distances; see Goobar & Leibundgut (2011) for a recent review. Yet, SNe Ia close enough to allow for detailed scrutiny of their physical properties are very rare, especially in a galaxy like M82, the host of several recent core-collapse SNe (Mattila et al. 2013; Gendre et al. 2013). At an estimated distance to M82 of 3.5 Mpc (Dalcanton et al. 2009), SN 2014J is the closest identified SN Ia in several decades, possibly rivaled by SN 1972E in NGC 5253 (Ardeberg & de Groot 1973) and SN 1986G in NGC 5128 (Phillips et al. 1987). Thus, SN 2014J is exceptionally well-suited for follow-up observations in a wide range of wavelengths, from radio to gamma-rays. These have the potential to yield transformational new clues into the progenitor systems of SNe Ia, as well as the detailed properties of dust along the line of sight, key astrophysical unknowns for the study of the accelerated expansion of the universe.

There is strong evidence that SNe Ia arise from thermonuclear explosions of carbon–oxygen white dwarfs (WDs) in binary systems (Nugent et al. 2011; Bloom et al. 2012). However, the nature of the second star remains unclear. For a long time, the preferred scenario was the single degenerate (SD) model (Whelan & Iben 1973), where a WD accretes mass from a hydrogen or helium rich donor star, thus becoming unstable while approaching the Chandrasekhar mass. The double-degenerate (DD) model involving the merger of two WDs (Tutukov & Yungelson 1981; Iben & Tutukov 1984; Webbink 1984) has gained considerable observational support in recent years; see, e.g., Wang & Han (2012).

In this work, we search for potential signatures of an SD progenitor system, such as variable Na D lines, precursor nova eruptions, features in the early light curve, radio emission, or a coincident source in pre-explosion in Hubble Space Telescope (HST) images.
2. DISCOVERY AND CLASSIFICATION

SN 2014J was discovered by Fossey et al. (2014) in \( BV \) and \( R \)-band images of M82 obtained on 2014 January 21.81 UT at UCL’s University of London Observatory. We have performed image subtractions using pre-explosion data from the Palomar P60 telescope as reference, calibrated with nearby stars listed in the APASS catalog\(^{22}\) yielding a discovery magnitude of \( R = 10.99 \pm 0.03 \) mag. The discovery image (S. Fossey 2014, private communication) and the P60 reference image, as well as the difference between the two are shown in Figure 1, along with the pre-explosion \( HST \) images (GO:11360, PI: R. O’Connell; GO:10776, PI: M. Mountain). The relative position of SN 2014J with respect to neighboring stars (middle panel) was established using multiple short exposures in the \( K \) band with adaptive optics and the NIRC2 wide camera at Keck (Tendulkar et al. 2014). In Section 5 we present a detailed analysis of the pre-explosion data.

A classification spectrum was obtained by the intermediate Palomar Transient Factory (iPTF) team on January 22.30 with the Dual Imaging Spectrograph on the ARC 3.5 m telescope (Cao et al. 2014), and in the near-IR using the MOSFIRE instrument at Keck. The combined spectra are shown in the bottom panel of Figure 1, while the photometry collected so far is displayed in Figure 2. The object shows characteristic spectral features associated with SNe Ia, e.g., similar to SN 2011fe (Pereira et al. 2013; Hsiao et al. 2013). However, the steep attenuation of the spectrum at short wavelengths is indicative of unusually large extinction by dust in the line of sight. A good match to the overall spectral energy distribution is found invoking a pronounced color excess, \( E(B - V)_\text{host} \approx 1.2 \) (\( R_V = 1.7 \)), and \( E(B - V)_\text{MW} = 0.14 \) (\( R_V = 3.1 \)) (Schlafly & Finkbeiner 2011), as shown in Figure 3. For the comparison, the spectra of SN 2011fe were artificially reddened assuming a Milky Way type extinction law (Cardelli et al. 1989), where both the color excess and \( R_V \) were allowed to vary freely. The spectrum favors a low value of the total-to-selective extinction, \( R_V \lesssim 2 \), as also suggested by spectropolarimetry observations by Patat et al. (2014). Low values of \( R_V \) are not unusual in SNe Ia, especially in the cases of high extinction; see, e.g., Nobili & Goobar (2008).

3. THE iPTF-LED MULTI-WAVELENGTH MONITORING OF SN 2014J IN M82

As a part of its continuous survey of the sky in the search for transients, iPTF has monitored M82 since 2009 October, with nearly daily cadence over the several months each year when M82 is visible from Palomar. The most recent campaign started on 2013 November 28. For the periods around full moon
we present a time-series spectral comparison also shows light curve fits in the direction of M82 (see inset panel in \( \text{H}\alpha \)). The SN was found in several observations from the iPTF narrowband survey, starting just hours after the fitted common offset was applied to connect with the data points in the pre-discovery optical, near-IR, and mid-IR light curves carefully monitoring the \( \text{H} \alpha \) narrowband detections are shown (black circles and inset image), S-corrected (Stritzinger et al. 2002) to the \( R \) band. Due to lack of accurate absolute calibration for the \( H_{\alpha} \) filters, a common offset was applied to connect with the data points in the pre-discovery light curve presented in Zheng et al. (2014). We also show their two fits of \( t_0 \), suggesting our first detection could be within \( \pm 5 \) hr from the onset of the supernova.

\[ E(B-V)_{\text{host}} = 1.22 \pm 0.05 \text{ mag and } R_V = 1.4 \pm 0.15. \]

We expect the accuracy of the fitted parameters to improve, as the light curve shape estimate will profit from the decreasing part of the SN light curve. However, the available data clearly puts \( R_V \) well below the Galactic average value, \( R_V = 3.1 \).

We also obtained two 1800 s high-resolution \( (R = 40,000) \) spectra with SOPHIE at Observatorie Haute-Provence on January 26.0 and January 28.0. Further, two 1800 s spectra \( (R = 67,000) \) were obtained with the Fibre-fed Echelle Spectrograph (FIES) on January 27.3 and another on February 1.0 with the Nordic Optical Telescope.

All spectra reveal deep multiple component Na\( \dagger \)D absorption and diffuse interstellar bands (DIBs), including \( \lambda \lambda 5780, 5797, 6284, \) and 6614, also reported by Cox et al. (2014) and Kotak (2014). The SOPHIE spectra further contain well resolved \( \text{Ca} \dagger \) \( H \) & \( K \) with features matching those of the Na\( \dagger \)D lines, shown in the co-added spectrum in Figure 4. We have not detected any significant time evolution for any of the resolved components of the Na\( \dagger \)D doublet over the four epochs (at the \( \sim 10\% \) level for 3\( \sigma \)), thus motivating the combination of the spectra.

Following the procedure outlined by Phillips et al. (2013), we measure the EW of the \( \lambda 5780 \) DIB to derive an independent estimate of host galaxy extinction for SN 2014J. We find \( \text{EW}(5780) = 0.48 \pm 0.01 \text{ Å} \) corresponding to \( A_V^{\text{host}} = 2.5 \pm 1.3 \text{ mag} \).

Given the low recession velocity of M82, it is difficult to separate the contribution from the Milky Way and the SN host galaxy absorption. However, the availability of \( \text{H} \dagger \) data from the LAB survey in the direction of M82 (see inset panel in Figure 4; Kalberla et al. 2005) clearly indicates which features are Galactic. Hence, all the absorption features redshifted with respect to the Milky Way are due to intervening material in M82.

4. SPECTRAL MODELING

In Figure 3 we present a time-series spectral comparison between SN 2011fe and SN 2014J starting roughly 12 days before peak brightness. The SNe are remarkably similar in their spectral evolution. The main differences seen are that the overall velocities are higher in SN 2014J (see the inset \( \text{Si} \dagger \) velocity plot) and there is a strong signature of high-velocity \( \text{Si} \dagger \) features with the latter two having both photospheric and high-velocity components. We see that SN 2014J more closely resembles SN 2005cf with respect to the high-velocity \( \text{Si} \dagger \) and \( \text{Ca} \dagger \) features which extend easily over the range of \( 20,000-30,000 \text{ km s}^{-1} \). Unlike either SN 2005cf or SN 2011fe, \( \text{C} \dagger \), \( \text{O} \dagger \), \( \text{Mg} \dagger \), \( \text{Si} \dagger \), and \( \text{Ca} \dagger \) with the latter two having both photospheric and high-velocity components. We see that SN 2014J more closely resembles SN 2005cf with respect to the high-velocity \( \text{Si} \dagger \) and \( \text{Ca} \dagger \) features which extend easily over the range of \( 20,000-30,000 \text{ km s}^{-1} \). Unlike either SN 2005cf or SN 2011fe, \( \text{C} \dagger \), \( \text{O} \dagger \), and \( \text{Mg} \dagger \) are absent at this phase in SN 2014J.

We searched for the presence of \( \text{C} \dagger \) \( \lambda 1.0693 \text{ \mu m} \) line in our NIR spectra, but the signal-to-noise is too low to do a meaningful fit comparable to that done for SN 2011fe (Hsiao et al. 2013). We do note that due to the stronger than average Mg\( \dagger \) features seen in the optical for SN 2014J, this analysis may be more

\[ \text{EW}(5780) = 0.48 \pm 0.01 \text{ Å} \]
Figure 3. Pre-max spectroscopic follow-up of SN 2014J, starting 7.6 days from estimated supernova onset using the ARC 3.5 m DIS, LCOGT FLOYDS, NOT ALFOSC, and P200 DBSP spectrographs. Spectra of SN 2011Fe (Pereira et al. 2013) at similar epochs (gray lines, reddened by $E(B-V)_{\text{host}} = 1.2$ mag with $R_V = 1.7$ and $E(B-V)_\text{MW} = 0.14$ mag with $R_V = 3.1$ are shown for comparison). The inset panel shows that SN 2014J has higher Si II velocity than SN 2011Fe and a steeper velocity gradient (Benetti et al. 2005).

Figure 4. Normalized Na I D doublet, plotted with solid vertical lines indicating the Galactic rest-frame wavelengths and the dashed vertical lines correspond to the mean velocity of M82 (203 km s$^{-1}$). The inset panel shows the velocity distribution of Ca II H & K (green and red lines) and the λ5780 DIB (black). Additionally, the H I λ21 cm emission spectrum of the line of sight of M82 from the LAB survey (Kalberla et al. 2005) is plotted (dashed gray line). The features of the Na I D and Ca II H & K, at approximately −50 and 0 km s$^{-1}$ with respect to the Galactic rest frame can be attributed to absorption in the Milky Way. The main Na I D absorption features, saturated between 74–135 km s$^{-1}$, originate in M82.
challenging, even with higher quality spectra, as the presence of Mg II $\lambda 1.9097 \mu$m should be quite strong as well.

Several explanations for the origin of the high-velocity features have been presented, from density enhancements via swept up circumstellar material (CSM) (Gerardy et al. 2004; Tanaka et al. 2006) to mixing or more complete burning in the outer layers of the SN (Mazzali et al. 2005a, 2005b) to ionization effects in the outer layers (Blondin et al. 2013). What is clear is that the features do offer a unique diagnostic for understanding properties of the progenitor system and/or the explosion mechanism and correlations between the strength of these features and the underlying colors and light curves of the SNe Ia (Childress et al. 2014; Maguire et al. 2013).

SN 2014J is among a class of SNe Ia where high-velocity features are present yet little to no evidence for C II exists even in very early spectra (see the broad-line or high-velocity gradient examples in Parrent et al. 2011). Since extensive UV data from HST exists for both SNe 2005cf and 2011fe, it will be interesting to see which of these supernovae SN 2014J most closely matches with respect to both the color and luminosity evolution.

5. THE QUEST FOR THE PROGENITOR SYSTEM

M82 has been extensively imaged by HST, thus it is possible to study the environment of the SN prior to the explosion. Because of the large attenuation due to dust in the line of sight, we concentrate on the NIR bands. We perform aperture photometry on the nearest sources to SN 2014J, shown in Figure 1. The closest object (yellow circle in Figure 1) falls $0.2'$ from the current best estimate of the SN location (R.A. = $9^h 55^m 42.217(1)$, decl. = $69^\circ 40' 26" 56.4(4)$ in J2000 coordinates with respect to the HST image; Tendulkar et al. 2014), corresponding to a 4$r$ spatial offset. For this source, we measure AB magnitudes of $F_{110W} = 21.4 \pm 0.4$, $F_{128N} = 21.9 \pm 0.4$, $F_{160W} = 20.6 \pm 0.4$, $F_{164N} = 21.2 \pm 0.4$. The error is dominated by the uncertain background subtraction as a result of source confusion.

The $F_{110} - F_{160}$ color is typical of other sources near this position. At a distance of 3.5 Mpc, the corresponding absolute magnitude of the nearest resolved object is $M_H \sim -19$ mag ($M_V < -9$ mag). This source could represent a stellar cluster, a grouping of unrelated objects or a region of relatively low dust attenuation.

Next, we consider the possibility that the source is a donor star in the SD scenario. The derived luminosity would then suggest a very luminous red supergiant. However, in the case where an SN originates from a system with CSM created by a mass-loss from a donor star, the interaction between the SN ejecta and the CSM is expected to give rise to radio emission (Chevalier 1982, 1988). The radio null-detections on January 23 and 24 (Chomiuk et al. 2014; Chandler & Marvil 2014) can therefore be used to derive an upper limit on the mass-loss rate. Adopting an SN shock-wave velocity of $3 \times 10^4$ km s$^{-1}$ (about twice the Si II velocity; see Figure 3), and similar parameters as assumed by Horesh et al. (2012) for SN 2011fe, the upper limit on the mass-loss rate is $M < 7 \times 10^{-8}(w/100$ km s$^{-1}) M_{\odot}$ yr$^{-1}$, where $w$ is the mass-loss wind velocity. The upper limit is compared to the ones obtained for SN 2011fe (Horesh et al. 2012; Chomiuk et al. 2012). Given these tight limits and the spatial displacement, we conclude that the closest resolved source in the pre-explosion HST images is unlikely to be a donor star.

Finally, we note that the $F_{110} - F_{160}$ color map shown in the middle right panel of Figure 1 suggests that SN 2014J is at the edge of a dust patch, about 4 pc in projected size. Light echoes may thus be expected for this SN.

We have searched for possible nova outbursts in the historic P48 R-band data covering a period of about 1500 days prior to the detection of SN 2014J. By binning the data in bins of 15 days, we do not find any excess larger than 4$r$ (calculated using the bootstrap technique; see Efron 1982). Our limiting magnitude is $R > 19.5$ mag for a total time span of 1000 days, and $R > 20.25$ mag for more than 765 days in this 1500 day time...
window. Assuming $A_R = 2$ mag, compatible with the extinction we estimate based on the SN colors, this corresponds to absolute magnitudes $M_R = -10.2$ and $-9.5$ respectively at the distance of M82. However, given the uncertainties on the properties of recurrent novae, see, e.g., Tang et al. (2014), we refrain from drawing firm conclusions against the possibility of recurrent novae preceding SN 2014J based on these non-detections.

6. SUMMARY AND CONCLUSIONS

The discovery of SN 2014J presents us with a unique opportunity to explore the physics of Type Ia SNe and the line-of-sight effects due to intervening matter. Further understanding in these areas is of utmost importance for the use of SNe Ia in cosmology. The early data from P48, starting as early as only hours from the explosion, and the multi-wavelength follow-up by the iPTF team covers an important range of the available windows in the electromagnetic spectrum. Just as the light curve reaches its maximum, we have learned that the SN has suffered non-standard extinction. We have searched for, but not detected, any time variation in our high-resolution spectra of the Na I D doublet. Similarly, we do not detect any pre-explosion activity in the $\sim 1500$ days of P48 monitoring. In a study of pre-explosion $HST$ images in the near-IR, the nearest resolved source is found 0'2 away from the SN location. The source brightness and offset from the SN makes it unlikely to be a donor star in a single-degenerate scenario.

Further, we make a first study of the spectral features of SN 2014J and find that it exhibits high-velocity features from intermediate mass material but lacks C and O often seen in very early spectra. Otherwise, it is a very similar to several well-studied normal SNe Ia.

We thank S. Fossey for making the discovery R-band image of SN 2014J available to us. We are grateful to S. Fossey and M. Phillips for helpful comments on the manuscript. We acknowledge A. McKay, A. Bradley, N. Scoville, P. L. Capak, C. M. Carollo, S. Lilly, H. Sheth, V. Bhalerao, P. Donati, S. Geier, F. Saturni, G. Nowak, and A. Finoguenov for cooperating with ToO observations. A.G. and R.A. acknowledge support from the Swedish Research Council and the Swedish Space Board and A.G.-Y. an ERC grant. M.M.K. acknowledges generous support from the Hubble Fellowship and Carnegie-Princeton Fellowship. Based on observations made with the Nordic Optical Telescope, operated by the Nordic Optical Telescope Scientific Association at the Observatorio del Roque de los Muchachos, La Palma, Spain, of the Instituto de Astrofísica de Canarias, Faulkes Telescope North image observed by Gain Lee, the Mount Abu 1.2 m Infrared Observatory, India, and the 1.93 m telescope of Haute-Provence Observatory, CNRS, France.
