36 **ABSTRACT**

37 Anthropogenic habitat disturbances are causing large-scale declines in animal abundance. For
38 many species, information on the drivers of decline is lacking or restricted to single sites, despite
39 calls for regional approaches. In this study, we determined the effect of different types of habitat
40 disturbance (natural or anthropogenic) and ecological factors on Geoffroy's spider monkey (*Ateles*
41 *geoffroyi*) abundance using a regional approach. We selected this study species because of its high
42 degree of social flexibility and its endangered status. We surveyed 4 sites in the Yucatan Peninsula
43 and recorded the number of individual monkeys encountered along 72 line-transect segments each
44 measuring 500m. Habitat disturbance variables were obtained from open-access databases and
45 included distance to roads, presence and number of hurricanes, forest loss, and presence of forest
46 fires. Ecological factors were based on data collected during vegetation surveys and included
47 number and basal area of feeding tree species, and canopy height. We ran generalized linear mixed
48 models and found that monkey abundance was negatively affected by forest loss but positively
49 affected by the basal area of feeding trees. We therefore suggest that a combination of
50 anthropogenic and ecological factors affects spider monkey abundance. Spider monkey's high
51 degree of social flexibility may be a mechanism allowing them to adjust to changes in their
52 environment when canopy connectivity is not lost. Our results provide policy and conservation-
53 decision makers with key information to develop regional conservation plans. Additionally, our
54 methods can be used to identify the factors that affect the abundance of other mammal species.

55 **Keywords:** behavioural flexibility; conservation; forest loss; population monitoring; spider monkey

56

57 INTRODUCTION

58 Anthropogenic and natural habitat disturbances are the major drivers of change in species
59 abundance and distribution, currently threatening the survival of 1 million plant and animal species
60 (Díaz et al., 2019). Forest loss increases human access to previously undisturbed areas and impacts
61 the remnant habitat through fragmentation and edge effects (Fischer and Lindenmayer, 2007;
62 Haddad et al., 2015). In addition, tree species producing fruits favoured by frugivores are often
63 targeted by selective logging (Johns, 1988), or die out due to changes in microclimate (Laurance et
64 al., 2006). The loss of these tree species may reduce the availability of food resources and lead to
65 the decline of frugivore populations (Kirika et al., 2008) or cause animals to move into areas that
66 are less suitable and potentially closer to human settlements (Imong et al., 2014). Given this
67 scenario, animal species with long life histories and low population growth rates, such as many
68 primates, may go extinct in the wild (Fahrig, 2002; van Schaik, 2013).

69 A large degree of variability exists in how species abundance is affected by anthropogenic
70 disturbance, thereby justifying the need to examine individual species' responses (Irwin et al.,
71 2010). However, results relative to these responses are often inconclusive as studies are usually
72 limited to single sites where conditions or threats differ from other sites (Link *et al.* 2010, Kolowski
73 and Alonso 2012), hampering their use by conservation practitioners at sites where studies have not
74 been carried out. Recent calls have been made to examine the effects of habitat disturbance at larger
75 spatial scales, whereby the variable of interest is compared across multiple sites (or landscapes),
76 facilitating extrapolation of the results to other areas (Arroyo-Rodríguez and Fahrig, 2014;
77 Ordóñez-Gómez et al., 2015).

78 Although habitat disturbance may jeopardize biodiversity, persistence of animal species is
79 largely determined by a their degree of behavioural flexibility (i.e., animals' ability to change their
80 behaviour in response to a changing environment; Komers 1997, van Schaik 2013, Beever *et al.*
81 2017). Aside from flexibility in maintenance activities such as foraging, social flexibility may aid

82 animals in adapting to changing habitats. Spider monkeys (*Ateles* spp.) exhibit a high degree of
83 social flexibility (Chapman et al., 1995; Schaffner et al., 2012), living in large groups that are rarely
84 all together; instead, they form small subgroups that change membership over the course of the day
85 (i.e. fission-fusion dynamics; Aureli *et al.* 2008). This social flexibility enables spider monkeys to
86 respond rapidly to environmental changes by decreasing subgroup size when resources are limited
87 (Rodrigues, 2017; Schaffner et al., 2012), aiding them to cope with the immediate effects of habitat
88 disturbance, for example by foraging more efficiently (Kolowski and Alonso, 2012; Rodrigues,
89 2017; Schaffner et al., 2012).

90 Anthropogenic disturbance often occurs at an accelerated pace compared to changes in the
91 environment caused by natural processes, affecting the survival capacity even of those species with
92 high social flexibility. Species such as spider monkeys and chimpanzees (*Pan troglodytes*), are
93 experiencing drastic population declines, despite their high levels of social flexibility (Ramos-
94 Fernández and Wallace, 2008; Walsh et al., 2003). These declines may be caused by extensive
95 habitat loss as a result of logging, high levels of hunting or outbreaks of zoonotic diseases
96 (Strindberg et al., 2018; Walsh et al., 2003). Aspects of their life-history and dietary patterns make
97 spider monkeys more vulnerable to the effects of anthropogenic disturbances, despite their high
98 levels of social flexibility. Spider monkeys are highly frugivorous (Di Fiore et al., 2008), and their
99 population abundance is positively correlated with fruit-tree abundance (Mourthé, 2014), which in
100 turn is related to the size and quality of the habitat (Arroyo-Rodríguez and Mandujano, 2006).
101 Previous studies demonstrate that spider monkeys in fragmented landscapes can decrease their
102 dependence on ripe fruits by eating more leaves (Chaves et al., 2012; de Luna et al., 2017).
103 However, higher leaf consumption may lead to decreased body condition (Wallace, 2005), and it
104 remains unclear how the overall health and long-term survival of populations living in disturbed
105 habitats will be affected. In addition, spider monkeys are almost completely arboreal (Campbell et
106 al., 2005) and have large home ranges (Asensio et al., 2015), thereby requiring large areas of well-

107 connected habitat to maintain arboreal pathways and meet their feeding requirements (Ramos-
108 Fernández and Wallace, 2008). Their long inter-birth intervals and time to reach sexual maturity
109 (Vick, 2008) limit the time within which declining populations can recover (Ramos-Fernández and
110 Wallace, 2008). As a result, even though social flexibility is an effective mechanism to cope with
111 short-term disturbance it is unclear whether it aids spider monkeys to effectively respond to
112 accelerated, diverse, and long-term anthropogenic changes in their habitat.

113 We examined the effect of different types of habitat disturbance on the abundance of spider
114 monkeys at the regional scale in the Yucatan Peninsula, Mexico. We recorded the location along the
115 transect and the time of sighting of each independently moving spider monkey. An expanding
116 tourism industry along Mexico's Caribbean coastline has caused rapid growth of human population
117 and infrastructure in the Yucatan Peninsula in recent years (Ellis et al., 2017). Additionally,
118 hurricanes and forest fires are common in the same area (Ameca et al., 2019; Bonilla-Moheno,
119 2012; Mascorro et al., 2016). These different sources of disturbance along with the sparse
120 distribution of large feeding trees as a result of forest regeneration (Ramos-Fernández and Ayala-
121 Orozco, 2003) make the Yucatan Peninsula an ideal place to study the effects of habitat disturbance
122 on spider monkey abundance at the regional scale. We examined the effect of anthropogenic and
123 natural disturbance, as well as ecological factors, to evaluate which are the most relevant in
124 determining spider monkey abundance.

125

126 **MATERIAL AND METHODS**

127 Data were collected using 16 transects distributed across 4 study sites in the Yucatan
128 Peninsula (Figure 1): Otoch Ma'ax yetel Kooch Fauna and Flora Protected Area (hereafter OMYK:
129 20°38' N, 87°38' W), Calakmul Biosphere Reserve (hereafter Calakmul: 18°6' 19.41" N,
130 89°48'38.98" W), Los Arboles Tulum (hereafter Los Arboles: 20°17'50.5"N, 87°30'59.1"W), and
131 Bala'an K'aax Fauna and Flora Protected Area (hereafter Bala'an K'aax: 19°14'58"N,

132 89°20'30"W). Study sites were separated by a minimum distance of 38 km. The Yucatan Peninsula
133 is marked by a clear dry (January - May) and rainy season (June – December, see SMN, 2016).

134 We estimated the abundance of spider monkeys using line transect surveys (Peres 1999,
135 Chiarello 2000, Michalski & Peres 2005). The number of transects per site depended on the size
136 and logistical constraints of the site. When possible the distance between transects was set at a
137 minimum of 1 km; however, the shape and size of the study area affected the orientation and
138 distance between transects. The lengths of transects in the four study sites varied between 1.5 and 4
139 km (mean = 2.25 km), common transect lengths for arboreal primate surveys. The total length of
140 sampled transects was 13 km in OMYK, 3 km in Los Arboles, 11 km in Bala'an K'aax and 9 km in
141 Calakmul. The number of transects surveyed per site is presented in Table 1.

142 Each transect was walked six times throughout a full year (May 2015-June 2016; see Table
143 1 for the total survey effort at each site). Each transect was walked at least twice in the morning
144 (07:00-11:00) and twice in the afternoon (14:00-18:00), at least one month apart to increase
145 independence between replicates of the same transect and to control for the effect of seasonality on
146 spider monkey habitat use. Transects were walked at a speed of 1.0-2.6 km/hour (mean = 1.6
147 km/hour), in line with the recommended speed for this species to minimize observer impact on the
148 distribution of the study animals (Spaan et al., 2017). To ensure consistency between surveys at
149 different sites, the same person collected the data during all transect walks. In addition, field
150 assistants were trained in survey techniques and the identification of spider monkeys prior to
151 starting surveys at a site to aid spider monkey detection.

152 **DATA COLLECTION**

153 We recorded the location along the transect and the time each independently moving spider
154 monkey was sighted. Habitat disturbance variables were calculated from open-access databases
155 obtained from geographical information systems and remote perception and included the distance to
156 roads, the presence and number of hurricanes, forest loss, and the presence of forest fires.

157 Ecological factors were calculated from data we collected during vegetation surveys and included
158 the number of feeding tree species, basal area of feeding trees, and canopy height (Supplementary
159 Materials).

160

161 **ECOLOGICAL FACTORS**

162 To determine feeding tree abundance and diversity, we surveyed vegetation transects within
163 a strip width of 2 m along the entire length of all transects used for monkey surveys. We measured
164 all trees of a diameter at breast height (DBH) ≥ 5 cm and identified their species with the help of
165 expert local field assistants, a botanist, and appropriate field guides (Bohn et al., 2014; Durán et al.,
166 2000; Martínez and Galindo-Leal, 2002). Most specimen samples were verified in the herbarium at
167 the Centro de Investigación Científica de Yucatan, Merida, Mexico. Lianas were not recorded.
168 When trees had multiple stems, we measured each stem of DBH ≥ 5 cm separately (Worman and
169 Chapman, 2006), and considered it as an individual tree for subsequent analyses. Canopy height
170 was determined at 50 m intervals along the transects using a clinometer. We obtained the following
171 ecological variables from the vegetation transects: feeding tree basal area, feeding tree species
172 richness and canopy height. Unidentified tree species were not included in the calculations of
173 feeding tree basal area and feeding tree species richness which may therefore have been
174 underestimated. See Supplementary Materials for calculations of ecological and habitat disturbance
175 variables.

176 **DATA ANALYSIS**

177 We divided transects into 500 m segments and calculated the spider monkey count (i.e., the
178 number of independently moving individuals) for each segment (Rovero and Struhsaker, 2007;
179 Serckx et al., 2016). Given that the aim of our study was to examine the effect of different types of
180 habitat disturbance and ecological factors on the relative abundance of spider monkeys rather than
181 calculate population density, spider monkey counts were summed for the six surveys on the same

182 500 m segment. A previous study on *A. geoffroyi* suggests that repeated counts of the same
183 individual during surveys are rare (2.1% according to Spaan et al., 2017). We therefore expect any
184 potential error introduced into monkey counts as a result of including recounted individuals to be
185 minimal. We selected a transect segment length of 500 m to avoid a high number of segments with
186 no sightings and few segments with many sightings (which can occur if transect segments are very
187 short), while at the same time allowing predictor variables to be determined at a local scale (Serckx
188 et al., 2016). We segmented transects from the start of the transect using the COGO toolbox in
189 ArcMap 10.22.

190 We determined the effect of measures of anthropogenic and natural habitat disturbance and
191 vegetation structure on spider monkey counts using a general linear mixed model (GLMM) (Barelli
192 et al., 2015; Rovero et al., 2012). We ran a Poisson GLMM with a square root link using the *glmer*
193 function of the package *lme4* (Bates et al., 2015) in the program R v. 3.2.1 (R Core Team, 2018).
194 Spider monkey count was entered as the dependent variable into the model. The predictor variables
195 were the distance to roads, distance to villages, forest loss, presence and number of hurricanes, the
196 presence and number of forest fires, the number of feeding tree species, canopy height and basal
197 area of feeding trees. Before entering predictor variables into the GLMM, all continuous variables
198 were z-transformed to a mean of 0 and a standard deviation of 1 (Schielzeth, 2010) so that estimates
199 could be compared irrespective of their scale (Kirkpatrick et al., 2017). We used a Variance
200 Inflation Factor (VIF) to assess the collinearity between predictor variables (Sikkink et al., 2007).
201 When there is collinearity between predictor variables it can be difficult to separate the independent
202 effects of each predictor variable on the dependent variable, complicating the interpretation of the
203 results (Rhodes et al., 2009; Freckleton et al., 2011). High VIF values (> 3) of a predictor variable
204 indicate collinearity with the other variables (Zuur et al., 2010). The variables number of forest
205 fires, the presence of hurricanes, and the distance to villages were excluded from further analysis
206 due to high VIF values. We accounted for overdispersion by adding an observation-level random

207 factor to the model (Harrison, 2014). We found no evidence of spatial autocorrelation (Moran's
208 Index = -0.03, $p = 0.89$), using the Spatial Autocorrelation tool in ArcMap 10.2.2.

209 To control for multiple segments of the same transect, we entered transect ID as a random
210 factor in the GLMM (Bolker et al., 2009). To control for multiple transects located at the same site,
211 we entered Site ID as a fixed control variable in the model as there were four study sites and
212 therefore not sufficient levels (<8 levels) to enter the variable as a random factor (Bolker, 2015).
213 We compared the full model to a null model using a likelihood ratio test (Barelli et al., 2015;
214 Forstmeier and Schielzeth, 2011) with the *ANOVA* function in R. The null model contained the
215 random factor transect ID and the observation-level random factor, along with site ID as a fixed
216 control variable. We calculated the marginal R^2 (variance explained by the predictor variables) of
217 the full model using the *r.squaredGLMM* function of the package *MuMIn* (Barton, 2018; Nakagawa
218 and Schielzeth, 2013). We do not present the conditional R^2 (variance explained by the predictor
219 variables and random factors combined) because the value is misleading given that the observation
220 level random effect is of little biological interest but its addition inflates the random effect variance
221 (Harrison, 2014; Harrison et al., 2018).

222 **RESULTS**

223 We recorded a total of 116 individual monkeys during transect walks at the four sites for an
224 overall encounter rate of 0.54 individuals per km walked. Sites ranged from 8 - 64 individuals and 4
225 -16 subgroups sighted during surveys (Table 1). Spider monkeys were sighted on 17 of the 72
226 transect segments (23.6%). The total number of individuals sighted in each of the 17 segments
227 during 6 transect walks ranged from 1 to 25 and the total number of subgroups from 1 to 6.

228 The GLMM results confirmed that predictor variables affected individual spider monkey
229 counts (likelihood ratio test comparing the full and null models: $X^2 = 17.23$, $df = 7$, $p=0.016$).
230 Feeding-tree basal area was positively correlated, and forest loss negatively correlated with spider
231 monkey counts (Table 2). Furthermore, the presence of forest fires tended to be negatively
232 correlated with spider monkey counts (Table 2). There was no effect of distance to roads, number of
233 hurricanes, feeding tree species richness and canopy height on spider monkey counts. The marginal
234 R^2 value was 0.16.

235 **DISCUSSION**

236 Our analysis at the regional scale found that spider monkey abundance in the Yucatan
237 Peninsula was possibly associated with anthropogenic habitat disturbance and food abundance. As
238 expected, we found higher numbers of spider monkeys in areas with more forest and more feeding
239 trees. Unlike previous studies on the effects of anthropogenic disturbances on spider monkeys (Link
240 et al., 2010), our results were not obtained at single sites, but instead at 4 sites across the Yucatan
241 Peninsula.

242 Forest loss is one of the main drivers of population declines of primate species (Estrada et
243 al., 2017), including spider monkeys (Ramos-Fernández and Wallace, 2008), as they have large
244 home range requirements and need large tracts of connected forest (Benchimol and Peres, 2013).
245 Given that we found forest loss to affect monkey populations within protected areas, it is safe to
246 assume that its effect outside of protected areas would be even more severe. Historically, forest loss

247 in the Yucatan Peninsula has been associated with slash-and-burn agriculture, where cleared areas
248 area left to regenerate after a few years of use (Dupuy et al., 2012; Hartter et al., 2008) and
249 therefore, forest loss was often only temporal. Recently, however, forest loss has been caused by
250 large-scale infrastructure expansion and urbanization (Ellis et al., 2017), where forest is cleared
251 permanently and replaced with concrete structures and roads. We found no effect of the distance to
252 roads on spider monkey counts. One possible reason is that such roads do not have a strong impact
253 on nearby forests. For example, tree species diversity and richness in mature agroforests managed
254 by Yucatec Mayan and Yucatec-Tzotzil villages surrounding the Calakmul Biosphere Reserve did
255 not differ from nearby mature forests (Bohn et al., 2014). Therefore, although roads leading to
256 villages may cause some deforestation, their floristic composition may encourage the use of these
257 areas by spider monkeys. However, if connected forests continue to shrink or disappear in this
258 region, we expect monkey population numbers to decline drastically. Under this scenario, it
259 becomes imperative to protect areas of continuous forest and well-connected forest patches to
260 ensure the sustained presence of spider monkeys in the Yucatan Peninsula.

261 An important source of forest loss is forest fires, which can clear away large swathes of
262 forest and are common during the dry season in the Yucatan Peninsula (Ellis et al., 2017). We found
263 a trend that the past occurrence of forest fires negatively affected the abundance of spider monkeys.
264 However, the lack of collinearity between the variables forest loss and the presence of forest fires
265 assessed through VIF indicates that forest loss affects the abundance of spider monkeys
266 independently from forest fires.

267 In line with our expectations and as previous studies on primates have suggested (Hanya and
268 Chapman, 2012), the abundance of feeding trees positively affected spider monkey abundance.
269 Contrary to our expectation, canopy height did not affect spider monkey abundance. Canopy height
270 is a measure of forest maturity in the Yucatan Peninsula, where forests are in differing stages of
271 regeneration due to slash-and-burn agriculture and hurricanes (Bonilla-Moheno, 2012; Chazdon,

272 2014), and older forests are taller than younger forests (Dupuy et al., 2012). Our result therefore
273 supports previous studies which have suggested the use of regenerating forest by spider monkeys
274 (Chapman 1989, Ramos-Fernández *et al.* 2013, Arroyo-Rodríguez *et al.* 2017, Bolt *et al.* 2018),
275 although they may prefer mature forest due to the higher availability of food (van Roosmalen and
276 Klein, 1988). For instance, tree species important in their diet occur at much higher densities in
277 mature compared to regenerating forest (e.g., 288 *Brosimum alicastrum* trees/ha in mature forest vs.
278 1 tree/ha in regenerating forest, Ramos-Fernández & Ayala-Orozco 2003). Therefore, although
279 spider monkeys can use regenerating forest they may rely on regular access to mature forest.
280 Mature forest fragmentation in the Yucatan Peninsula differs from other regions in Mexico where
281 spider monkeys occur (e.g., Veracruz and Chiapas; Galán-Acedo *et al.* 2018) in that forest patches
282 are surrounded by a matrix of forest in differing stages of regeneration (Daniels et al., 2008;
283 Urquiza-Haas et al., 2007). This results in a patchy distribution of feeding trees and a complex
284 network of spatially and temporally available food sources for spider monkeys. Importantly,
285 although food availability is lower in regenerating forests (García-Licona et al., 2014), canopy
286 connectivity is maintained, potentially allowing arboreal species with high degrees of social
287 flexibility to use regenerating forests as a corridor connecting mature forest patches. This is because
288 high degrees of social flexibility allow species to adjust their subgroup size and composition in
289 relation to food availability (Schaffner et al., 2012), and may enable them to include well connected
290 areas with low food availability into their home range. Social flexibility may therefore be a
291 mechanism allowing spider monkeys to adapt to changes in their environment caused by natural or
292 anthropogenic disturbances so long as canopy connectivity is not lost. To understand the importance
293 and conservation value of regenerating forests for arboreal mammals, future studies should focus on
294 habitat use at the regional scale and the importance of mature forest patches in a mosaic of
295 regenerating forest, with conservation efforts focused on both maintaining mature forest and
296 promoting forest regeneration.

297 By collecting data from different sites across the Yucatan Peninsula, we were able to
298 investigate how different types of disturbance and environmental factors may affect the abundance
299 of an endangered primate at a regional scale. Our results indicate that spider monkey abundance in
300 the Yucatan Peninsula is driven more by overall forest loss than human infrastructure (e.g., distance
301 to roads) and factors affecting forest structure and composition (e.g., number of hurricanes).
302 Additionally, we suggest that it is a combination of anthropogenic and ecological factors that affect
303 the species' abundance. Forested spider monkey habitat is being converted at an unprecedented rate
304 along with Caribbean coastlines due to the continually expanding tourism industry and frequent
305 forest fires in the interior areas of the Yucatan Peninsula (Ellis et al., 2017). Continued forest loss
306 will almost certainly result in drastic spider monkey population declines. This information is
307 extremely useful to develop regional conservation plans as the information obtained from single
308 sites, though valuable for understanding conditions at one location, may not be applicable to other
309 sites in the same region. We recommend similar studies be conducted on the same species at
310 multiple locations and on other species at the same locations to draw species-specific and/or
311 regional inferences on how habitat disturbance affects species abundance, thereby aiding
312 conservation decision-making.

313

314 **ACKNOWLEDGEMENTS**

315 We would like to thank Karla Hernandez Hernandez, Braulio Pinacho-Guendulain and local field
316 assistants in Bala'an K'aax, Calakmul, Otoch Ma'ax yetel Kooch and Los Arboles for assistance
317 with data collection. We thank Alfredo Dorantes Euán for help in identifying tree species and Dr. V.
318 Sosa Fernández, Dr. R. Guevara-Hernández and Dr. V. Arroyo-Rodríguez for advice on the
319 analyses. We would also like to thank Operation Wallacea, the Instituto Politécnico Nacional,
320 Instituto de Ecología, A.C., the Instituto de Neuroetología of the Universidad Veracruzana and Los
321 Arboles Tulum for logistical support. This work was supported by the Consejo Nacional de Ciencia
322 y Tecnología [CONACYT: CVU: 637705]; CONANP [PROCER/DRPYyCM/2/2015]; National
323 Geographic Society [9784-15]; and Chester Zoo. Research complied with protocols approved by
324 the Secretaría del Medio Ambiente y Recursos Naturales [SEMARNAT: SGPA/DGVS/10405/15]

325 and adhered to the legal requirements of Mexico. The Comisión Nacional de Áreas Naturales
326 Protegidas (CONANP) and Los Arboles Tulum gave us permission to conduct surveys in the four
327 protected areas. We thank Dr. Emmanuel Serrano and one anonymous reviewer for their comments
328 on this manuscript.
