18 Abstract

19 Entomopathogenic nematodes (EPN) are globally important inundative biological control agents.  
20 Their widespread use makes environmental risk assessment important, but very few  
21 comprehensive post-application risk assessments have been conducted for EPN. We apply a  
22 rigorous risk analysis procedure to the use of EPN applied in a forest ecosystem to suppress the  
23 large pine weevil (*Hylobius abietis*). In this synthesis, we provide a quantitative evaluation of  
24 five risk categories: a) establishment, b) dispersal, c) host range, d) direct non-target effects and  
25 e) indirect non-target effects. A low level of risk was identified (35 – 51 out of a possible total of  
26 125). Species exotic to the clear-fell forest ecosystem (*Steinernema carpocapsae* and  
27 *Heterorhabditis downesi*) were accorded a lower overall risk status than native species and  
28 strains (*Steinernema feltiae*), largely as a result of their shorter persistence in the target  
29 environment. We conclude that EPN are a low risk viable alternative control for pine weevil  
30 compared to the higher risk conventional control using pyrethroid or neonicotinoid insecticides.

35

36 Inundative control with EPN and the potential associated risks

37 Entomopathogenic nematodes (EPN) are lethal insect pathogens that are commercially produced  
38 as inundative control agents and used in various regions of the world against a variety of pests  
39 (Kaya & Gaugler, 1993; Shapiro-Ilan et al., 2006; Grewal, 2012). There are two genera  
40 (*Steinernema* Travassos, 1927 and *Heterorhabditis* Poinar, 1976: Nematoda: Rhabditidae), both  
41 of which have global natural distributions (except Antarctica) and are used in biological control  
42 (Kaya & Gaugler, 1993; Stuart et al., 2006). The free-living stage of the life cycle, the infective  
43 juvenile (IJ), seeks out an insect host, invades it and releases entomopathogenic bacteria from its  
44 gut that kill the insect within days (Kaya & Gaugler, 1993; Forst, 1997; Lewis et al., 2006). The  
45 nematodes feed on the bacteria, reproduce and, typically after a period of two to three weeks, up  
46 to several hundred thousand IJs leave the host cadaver to seek out new hosts. Since EPN have a  
47 wide potential host range (Peters, 1996), can survive and reproduce in the field (Bathon, 1996;  
48 Smits, 1996) and may disperse, including via phoresy (Eng et al., 2005; Campos-Herrera et al.,  
49 2006) or transport by mobile susceptible hosts (Downes & Griffin, 1996), they have the potential  
50 to cause environmental impacts other than the intended pest reduction.

51 For assessing the risk of using inundative biological control organisms, van Lenteren et al.  
52 (2003) identified five commonly agreed risk categories: host range, dispersal, establishment, and  
53 direct and indirect non-target effects. To standardize risk assessment procedures, protocols for  
54 assessing the risk of invertebrate biological control organisms in each of these categories have  
55 been proposed (e.g. Babendreier et al., 2005; Clerq et al., 2011). A number of reviews  
56 summarize the results of risk assessment studies on both classical and inundative biological  
57 control organisms (e.g. Hokkanen and Lynch, 1995; Ehlers & Hokkanen, 1996; Barratt et al.,

58 2006 & 2010; van Lenteren et al., 2006). For classical and augmentative biological control Hajek  
59 et al. (2016) have demonstrated widespread rather trivial effects of introductions and a few cases  
60 of direct and indirect impacts at the population and community level mainly for older (pre 1950)  
61 introductions. For EPN, extensive information exists relevant to the risk categories of  
62 establishment (or persistence) (e.g. Wright et al., 1993; Shields et al., 1999; Koppenhofer &  
63 Fuzy, 2006; Susurluk & Ehlers, 2008) and dispersal (e.g. Lacey et al., 1995; Jabbour &  
64 Barbercheck, 2008), as well as host range (Peters, 1996). Direct and indirect non-target impacts  
65 have received less attention (Bathon, 1996; Somasekhar et al., 2002; de Nardo et al., 2006;  
66 Hodson et al., 2012). The available evidence indicates that EPN are generally safe, with little  
67 environmental impact (Ehlers & Hokkanen, 1996), though there are very few examples of  
68 comprehensive post-application risk assessments investigating multiple risk categories. The only  
69 study that has so far investigated all five risk categories is that of van Lenteren et al. (2003) who  
70 evaluated the risk of *Steinernema feltiae* (Filipjev, 1934) application in an open field. The  
71 present case study summarises risk assessment research carried out on a range of EPN species  
72 used to control the large pine weevil (*Hylobius abietis* L., 1758; Coleoptera: Curculionidae) and  
73 evaluates the risk for strains that are both native and foreign to the target habitat using the  
74 protocol of van Lenteren et al. (2003).

#### 75 Large pine weevil control: Target pest, environment and control agents

76 The large pine weevil is a major forestry pest in 15 European countries, including Ireland and the  
77 UK (Långström & Day, 2004). This insect threatens an estimated 3.4 million hectares of forests  
78 and would cause up to € 140 million in annual damages if not controlled (Långström & Day,  
79 2004). Larvae feed and develop under the bark of stumps and roots of recently dead conifers for

80 one or more years (Leather et al., 1999). Emerging adults feed on the bark of seedlings that are  
81 planted to restock such sites, and this can result in up to 100 % of the seedlings being killed if the  
82 pest is not controlled (Heritage et al., 1989; Leather et al., 1999; Petersson et al., 2005). Forestry  
83 practices based on coniferous monoculture with clear-felling have favoured pine weevil, by  
84 providing an optimum breeding habitat in stumps, and populations can be very high on clear-fell  
85 sites (Leather et al., 1999).

86 EPN are currently being trialled in Ireland and the UK (including full operational application at  
87 selected sites) to evaluate their potential as inundative control agents within an integrated  
88 management strategy aimed at replacing pyrethroids (i.e. alpha-cypermethrin and cypermethrin)  
89 currently used to control pine weevil (e.g. Brixey et al., 2006; Dillon et al., 2006; Williams et al.,  
90 2013). To suppress weevil populations, EPN IJs in aqueous suspension are sprayed onto the soil  
91 around the circumference of each tree stump on a site-wide level (recommended rate  $3.5 \times 10^6$  IJs  
92 per stump) to target the immature stages (Dillon et al., 2006). Several EPN species have been  
93 tested: *Steinernema carpocapsae* (Weiser, 1955), *Steinernema kraussei* (Steiner, 1923) *S. feltiae*,  
94 *Heterorhabditis downesi* Stock, Griffin and Burnell, 2002 and *Heterorhabditis megidis* Poinar,  
95 Jackson and Klein, 1987 (Table 1) and all have shown potential to significantly reduce weevil  
96 populations and/or seedling damage (Brixey et al., 2006; Dillon et al., 2006; Torr et al., 2007;  
97 Williams et al., 2013). *Steinernema carpocapsae* is currently the main species in use due to its  
98 competitive cost and amenability to mass production, though other species (especially *H.*  
99 *downesi*) have shown better field efficacy.

100 Natural distribution of entomopathogenic nematode species used for pine weevil control

101 Organisms exotic to a particular environment may pose risks that differ in quality and scale from  
102 those of indigenous organisms (Simberloff & Stiling, 1996; van Lenteren et al., 2003; Clerq et  
103 al., 2011; van Lenteren, 2012). Ehlers and Hokkanen (1996) recommended that, unlike the  
104 release of indigenous EPN, the release of exotic EPN species (but not exotic strains of  
105 indigenous species) should be regulated due to greater potential risk. Thus, a discussion of the  
106 risks posed by EPN must take into consideration the known geographical distribution and natural  
107 habitats of the applied nematodes.

108 Surveys of EPN in Britain and Ireland have screened > 3000 soil samples collected from a  
109 variety of habitats (e.g. grassland, woodland, heathland, hedgerows) (Blackshaw, 1988;  
110 Hominick & Briscoe, 1990a & 1990b; Boag et al., 1992; Hominick et al., 1995; Gwynn &  
111 Richardson, 1996; Chandler et al., 1997; Dillon, 2003). To date, there exist only two records of  
112 *S. carpocapsae* in Britain (Georgis & Hague, 1979 & 1981), which have since been disputed (D.  
113 Hunt, CABI Europe UK, pers. comm.), and no record of this species in Ireland. A recent, as yet  
114 unpublished, study by Rae and colleagues has isolated *S. carpocapsae* from a gorse hedge and a  
115 wooded layby, both in Cornwall. Both these isolates were far away from forestry with nematode  
116 applications, but the authors are sequencing the mitochondrial DNA to be sure that they are  
117 different from the BASF-Becker Underwood strains, which are used commercially (R. Rae,  
118 LJMU UK, pers.comm.). While failure to detect a species does not confirm absence, based on  
119 the available evidence we consider *S. carpocapsae* to be exotic to both Britain and Ireland (Table  
120 1).

121 There are numerous records of *Steinernema feltiae* in Britain and Ireland (Blackshaw, 1988;  
122 Griffin et al., 1991; Boag et al., 1992; Hominick et al., 1995; Gwynn & Richardson, 1996;

123 Chandler et al., 1997; Dillon, 2003), some of which are from coniferous forest soils (Hominick  
124 & Briscoe, 1990a; Dillon, 2003; Harvey & Griffin, 2016). *Steinernema feltiae* strain 4CFMO  
125 was isolated by Dillon (2003) from a coniferous clear-fell site in Ireland and we thus consider it  
126 indigenous to this environment (Table 1). *Steinernema feltiae* strain EN02 is a commercially  
127 produced strain (e-nema GmbH, Germany) that was originally isolated in Germany (Dillon et al.,  
128 2008) and, though the species is indigenous to the UK and Ireland, we treat this strain as exotic  
129 to Irish coniferous forest (Table 1). *Steinernema kraussei* has likewise been recorded in Britain  
130 (Hominick et al., 1995), including in coniferous forest soil (Gwynn & Richardson, 1996). There  
131 is one unpublished record of *S. kraussei* from a coniferous clear-fell site in Ireland, confirmed by  
132 sequencing the rDNA internal transcribed spacer region (Harvey, unpublished data; Genbank  
133 Accession numbers: KU847415, KU847416). Harvey collected *S. kraussei* from a Sitka spruce  
134 (*Picea sitchensis* [Bong.] Carr.) clear-fell from a soil sample around a stump after it had been  
135 treated with *H. downesi* in Glendalough (53°03'N 006°28'W, elevation 300 m), which had been  
136 felled in 2004. Samples were identified from two separate extractions from bulk samples of  
137 several hundred to several thousand nematodes. There was some polymorphism detected, but this  
138 is not unusual for the ITS region and has been observed before for *S. feltiae*. The Genbank blast  
139 search confirmed the identity to be *S. kraussei* with 98-99% identity. *Heterorhabditis downesi* is  
140 indigenous to Britain and Ireland, but has so far been isolated only from sandy coastal soils  
141 (Griffin et al., 1994 & 1999). *Heterorhabditis megidis* has been isolated in Britain (Hominick et  
142 al., 1995; Hominick, 2002), but has likewise not been reported in forest soils (Hominick &  
143 Briscoe, 1990a; Gwynn & Richardson, 1996; Dillon, 2003). We therefore consider *H. downesi*  
144 and *H. megidis* indigenous to Britain (and, in the case of *H. downesi*, also Ireland), but exotic to  
145 coniferous forest plantations in the context of this case study (Table 1).

146 Risk categories for inundative control agents

147 Several methods to standardise risk assessment procedures for inundative control agents have  
148 been proposed (van Lenteren et al., 2003; Babendreier et al., 2005; Mills et al., 2006). To meet  
149 the criteria for risk assessment of introduced biological control agents recommended by the  
150 Organisation for Economic Co-operation and Development (OECD, 2003), van Lenteren et al.  
151 (2003) proposed a method of calculating a numerical index based on five risk categories. This  
152 method allows for a categorical and quantifiable evaluation of risk. The index value is obtained  
153 by estimating risk in each of the five categories based on specific criteria. The likelihood (very  
154 unlikely to very likely) and magnitude (minimal to massive) of risk are each assigned a value of  
155 1-5; the likelihood and magnitude values within each category are then multiplied and the  
156 products are added to arrive at the final index value which can range from 5 to 125, where a  
157 higher number indicates a greater environmental risk (van Lenteren et al., 2003). In the present  
158 paper, we follow this approach, using results from the pine weevil system complemented by  
159 literature from other contexts, to derive risk indices for EPN species *S. carpocapsae* (exotic to  
160 Ireland), *S. feltiae* (one strain indigenous and one strain exotic to Ireland) and *H. downesi*  
161 (indigenous to Ireland) when used against pine weevil in forestry. We have not included exact  
162 risk values for *H. megidis* and *S. kraussei*, the other two species that have been tested against  
163 pine weevil and for which fewer data are available. We estimate *H. megidis* to be similar to its  
164 close relative *H. downesi*, both being exotic to the habitat, and *S. kraussei* to be similar to *S.*  
165 *feltiae*, both species being present in the target habitat.

166

167

168 Risk of EPN application in forest ecosystem

169 a) Establishment

170 In inundative biological control, long-term persistence and establishment of the applied control  
171 agent in the target environment is not a desired outcome (Bathon, 1996; van Lenteren et al.,  
172 2003). Control agents are applied in large numbers to cause an immediate, but usually transient,  
173 reduction in the pest population. EPN have the potential to persist in the soil after application  
174 since the applied IJs are the non-feeding, stress-tolerant 'dauer' stage; in addition, they may  
175 recycle and multiply in the field by infecting insects (Kaya & Gaugler, 1993; Grewal et al.,  
176 2002). The extent and duration of post-application persistence of EPN is expected to vary with  
177 the applied species, field conditions and the abundance and suitability of hosts (target and non-  
178 target) (Smits, 1996; Barratt et al., 2010; Griffin, 2015). Though EPN numbers may be high in  
179 the short term (weeks to months), in most studies numbers decrease rapidly over time and EPN  
180 are usually no longer detectable within a year of application (Klein & Georgis, 1992; Wright et  
181 al., 1993; Smits, 1996; Kurtz et al., 2007). In a minority of cases however, EPN have been  
182 recorded more than a year after application (Shields et al., 1999; Susurluk & Ehlers, 2008;  
183 Parkman et al., 1996).

184 Dillon et al. (2008a) investigated the persistence of EPN in soil around pine stumps treated to  
185 suppress the large pine weevil in Irish trials. Four species were trialled: *H. megidis*, *H. downesi*,  
186 *S. carpocapsae* and two strains of *S. feltiae*, a commercial strain (EN02) and an indigenous Irish  
187 strain isolated from soil in a clear-felled coniferous forest (4CFMO) (Dillon, 2003; Dillon et al.,  
188 2008a). EPN corresponding to the genus applied to a stump (i.e. *Steinernema* or *Heterorhabditis*)  
189 were recovered up to three years after application (Dillon et al., 2008a), though recovery rates

190 decreased significantly over time: approximately 30 % of soil cores scored positive for EPN one  
191 month after application, but only approximately 9 % did so after three years. Four and five years  
192 after application, only *S. feltiae* was found, and it was recovered even around stumps treated with  
193 other EPN species. When these *S. feltiae* isolates were compared to the applied strains  
194 (indigenous 4CFMO and commercial EN02) using genome-wide molecular analysis (Amplified  
195 Fragment Length Polymorphism, AFLP), they were found to be more closely related to the  
196 indigenous strain 4CFMO than the exotic strain EN02 (Dillon et al., 2008a). Mesocosm  
197 experiments with more controlled conditions by Dillon et al. (2008a) also showed greater  
198 persistence of *S. feltiae* 4CFMO compared to *S. feltiae* EN02. Similarly, in a study conducted on  
199 UK coniferous forest sites, Torr et al. (2007) compared the persistence of exotic *S. carpocapsae*  
200 to that of indigenous *S. kraussei* (Table 1). One year after application, soil was sampled around  
201 tree stumps treated with  $3.5 \times 10^6$  IJs of either of the two species. There was a significant  
202 decrease in levels of both species over time, though less rapidly for *S. kraussei* (Torr et al.,  
203 2007). In addition, densities of *S. kraussei* were consistently higher than those of *S. carpocapsae*  
204 from six months after application. Thus, both Torr et al. (2007) and Dillon et al. (2008a) found  
205 that EPN species and strains exotic to the habitat persisted on clear-fell sites for shorter periods  
206 than indigenous species or strains, possibly due to the latter being better adapted to the target  
207 environment (Dillon et al., 2008a).

208

209 Dillon et al.'s (2008a) study compared various species in a uniform setting (pine stumps on deep  
210 peat soil), while Harvey and Griffin (2015) monitored persistence of a single species (*S.*  
211 *carpocapsae*) under varied conditions: lodgepole pine (*Pinus contorta* Douglas) and Sitka spruce  
212 stumps on peat (nearly pure organic matter) or mineral soil. Similar to the results obtained by

213 Dillon et al. (2008a), the percentage of soil cores with *S. carpocapsae* decreased significantly  
214 within the first two years after EPN application, from up to 12 % of cores after five months to 3  
215 % after two years (Harvey & Griffin, 2016). Five years after application, only indigenous  
216 *Steinernema* spp. were found around stumps (Harvey & Griffin, 2016). Similar results were  
217 obtained for stump bark: *S. carpocapsae* was found under the bark of up to 67 % of stumps one  
218 and two years after application, but was not detected there four or five years post application  
219 (Harvey & Griffin, 2016). The incidence of *S. carpocapsae* was positively correlated with the  
220 size of weevil populations in the stumps, suggesting that persistence of the EPN population was  
221 dependent on the population of pine weevils, in which they can reproduce (Pye & Burman, 1978;  
222 Dillon, 2003). Since stumps are suitable for pine weevil for only three to four years after felling  
223 (Leather et al., 1999), and EPN are usually applied 12 to 18 months after felling (Dillon et al.,  
224 2008a), this link between the target pest population and nematode persistence imposes a natural  
225 limit on EPN recycling and, therefore, reduces the risk of long-term persistence and  
226 establishment. A natural next step would be to extend these experiments to other EPN species,  
227 which are potential inundative biological control agents for pine weevil.

228 We conclude that exotic *S. carpocapsae* and *H. downesi* as well as exotic strain *S. feltiae* EN02  
229 used against the large pine weevil on clear-fell sites can persist by recycling in the target host in  
230 the short term, but that establishment four years or more post-infection is ‘unlikely’ (likelihood =  
231 2; Hickson et al., 2000; van Lenteren et al., 2003) (Table 2). Moreover, we consider the potential  
232 non-target habitat on coniferous clear-fell sites where these exotic EPN may establish to be  
233 ‘transient in time and space’ (van Lenteren et al., 2003), due to the apparent dependence of EPN  
234 on pine weevils for recycling (magnitude = 1; van Lenteren et al., 2003; Table 2). This agrees  
235 with similar studies on persistence in other, often very different settings (Smits, 1996; Susurluk

236 & Ehlers, 2008). The indigenous strain *S. feltiae* 4CFMO, however, was originally isolated from  
237 a coniferous clear-fell site and so is likely to be adapted to this habitat and to hosts there, other  
238 than pine weevil. Therefore, if it were applied to sites where it is not already present, it may  
239 persist for longer and in a greater area compared to exotic EPN. We therefore conclude that  
240 establishment of *S. feltiae* 4CFMO on coniferous clear-fell sites is ‘likely’ (likelihood = 4;  
241 Hickson, 2000; van Lenteren et al., 2003) and, because more than 50% of the area of coniferous  
242 clear-fell sites is soil available for colonisation by EPN, the potential area of establishment is  
243 ‘massive’ (magnitude = 5; van Lenteren et al., 2003) (Table 2). However, since it appears that  
244 native EPN may colonise clear-fell sites as part of a natural ecological succession, following  
245 colonisation by native grasses and the associated insect fauna (Harvey & Griffin, 2016), this  
246 ‘risk’ is essentially no different to that of a natural recolonisation event. A less conservative view  
247 would be that the risk of establishment for indigenous species necessarily represents the lowest  
248 risk possible and would therefore better fit the category of ‘very unlikely’ establishment,  
249 resulting in a numerical risk value of 1 for *S. feltiae* (van Lenteren et al., 20013). While  
250 establishment risk of EPN in coniferous clear-fell soils can be considered low overall based on  
251 these results, persistence for up to four years after application still provides a window of time in  
252 which they can disperse to other areas, potentially creating additional risk.

### 253 b) Dispersal

254 EPN disperse through soil as IJs which are typically about 0.5 – 1 mm in length. Depending on  
255 soil type, moisture content etc., the rate of horizontal dispersal of IJs after inundative application  
256 is usually a few centimetres per day and limited to a scale of meters overall (Poinar & Hom,  
257 1986; Downes & Griffin, 1996; Barratt et al., 2006). IJs of both *Steinernema* and *Heterorhabditis*

258 species can move through mineral and peat soils like those found on coniferous clear-fell sites  
259 (Kruitbos et al., 2010; Williams et al., 2013). In addition, IJs may follow lateral roots  
260 ('routeways') to locate and infect pine weevil larvae situated more than 50 cm from the point of  
261 application (Dillon et al., 2006; Ennis et al., 2012).

262 Dillon et al. (2008a) investigated the dispersal of EPN in the field and in mesocosms containing  
263 peat, simulating the type of soil typical of many coniferous plantations in Ireland and Britain. In  
264 mesocosms, a very low incidence of three EPN species (*S. carpocapsae*, *S. feltiae* 4CFMO and  
265 *H. downesi*) was detected 20 cm from the point of application, the maximum distance that was  
266 sampled. In the field, soil samples were three to four times more likely to score positive for EPN  
267 when taken at a treated tree stump compared to a distance of 20 cm from the stump (Dillon et al.,  
268 2008a). The distance from the stump at which EPN were found was not influenced by species:  
269 exotic species *S. carpocapsae* and *H. downesi* dispersed at a rate comparable to the indigenous *S.*  
270 *feltiae* 4CFMO. Harvey & Griffin (2016) likewise observed that the probability of detecting *S.*  
271 *carpocapsae* decreased significantly as distance from the stump increased from 0 cm to 60 cm.  
272 These findings are in general agreement with previous studies in different settings, where EPN  
273 presence decreases rapidly with distance from the point of application (Poinar & Hom, 1986;  
274 Smits, 1996; Barratt et al., 2006; Jabbour & Barbercheck, 2008).

275 Long-distance dispersal can occur, however, when facilitated by infected or externally  
276 contaminated host insects or other carriers. Transport in wind and water may also occur, though  
277 considered rare (Downes & Griffin, 1996; Griffin, 2015). The phoretic route is the most likely  
278 explanation for reports of rapid short-range dispersal (Jabbour & Barbercheck, 2008) or long-  
279 range dispersal over several hundred meters up to kilometres (Barratt et al., 2006). Following

280 application of *Steinernema scapterisci* (Nguyen and Smart, 1990) to control mole crickets in  
281 Florida, infected insects were collected as far as 23 km from the nearest site of application  
282 (Parkman et al., 1993 & 1996). Lacey et al. (1995) reported dispersal of *Steinernema glaseri*  
283 (Steiner, 1929) IJs on the cuticle or within the haemocoel of *Popillia japonica* Newman, 1841.  
284 Infected beetles in many cases contained enough nematodes to allow reproduction, and dispersal  
285 in the field over at least 50 m was reported. The potential for dispersal of EPN by adult pine  
286 weevil has been demonstrated in the laboratory (Kruitbos et al., 2009).

287 Dillon et al. (2008a) tested for wider dispersal of EPN from treated stumps but found no EPN at  
288 distances ranging from 1 to 10 m from the nearest treated stump. Harvey (2010) extended the  
289 sampling up to 100 m off-site. *Steinernema carpocapsae* was detected in a small proportion of  
290 samples collected 5 - 10 m from two of three sites where it had been applied 1-2 years previously  
291 (Harvey, 2010). When the areas at which each of these positive samples was detected were  
292 extensively re-sampled (40 bulk soil samples, each comprised of 5 subsamples at each previously  
293 positive spot) five years after application, only native *Steinernema* spp. were isolated (Harvey &  
294 Griffin, unpublished data). Failure to detect *S. carpocapsae* does not guarantee that no spread  
295 and/or establishment of this species off-site has occurred, but it does suggest that any *S.*  
296 *carpocapsae* populations that may have remained after five years are most likely small and  
297 isolated. Similar tests for other EPN should be undertaken to establish their potential for off-site  
298 spread.

299 The natural host range and the mechanisms underlying the persistence and patchy distribution of  
300 EPN populations in the wild are poorly understood (Stuart & Gaugler, 1994; Peters, 1996; Smits,  
301 1996; Griffin, 2015). However, given the results discussed here, the distance of dispersal within

302 and off clear-fell sites is unlikely to exceed 100 m (likelihood = 2; van Lenteren et al., 2003) for  
303 any of the EPN investigated and, given the large number of IJs applied per stump (approx.  $3.5 \times$   
304  $10^6$ ), the magnitude of any such dispersal will probably be ‘minimal’ (i.e. < 1 % of the applied  
305 EPN dispersing, magnitude = 1; van Lenteren et al., 2003), which is similar to previous  
306 evaluations of EPN dispersal risk (Smits, 1996; Barratt et al., 2006) (Table 2).

307

308

### 309 c) Host range

310 In laboratory assays, EPN have a broad host range: for example, *S. carpocapsae* was reported to  
311 kill >200 species of insects from 10 orders in close-contact laboratory assays (Poinar, 1979);  
312 however, the realised host range in the field is expected to be much narrower, and the range of  
313 insects affected to vary between species (Peters, 1996). Due to the wide potential host range,  
314 however, van Lenteren et al. (2003) assigned maximal risk values of 5 to both likelihood and  
315 magnitude of risk to *S. feltiae* when applied to an open field in Finland (> 30 species host range  
316 and taxon range > Order level, respectively; van Lenteren et al., 2003). We have adopted this  
317 evaluation of host range for all EPN species used against the large pine weevil in our risk index  
318 estimation (Table 2).

319

### 320 d) Direct non-target effects

321 Non-target impacts of inundatively applied EPN are of concern for three related reasons. Firstly,  
322 negative impacts on biodiversity are considered detrimental in sustainable management of

323 natural resources, as they are likely to reduce the resilience and function of an ecosystem  
324 (Bengtsson et al., 2000, Brockerhoff et al., 2008). Secondly, non-target insects that are of  
325 particular benefit to sustainable forest management (e.g. wood decomposers) may be at particular  
326 risk due to their proximity to the zone of nematode application (Harvey et al., 2012). Thirdly,  
327 non-target impacts have the potential to disrupt natural control of the pest if they affect an  
328 important natural enemy (van Lenteren, 2012; Harvey & Griffin, 2012). This last point is  
329 underlined by the fact that control by natural enemies, without intervention, may make a  
330 considerable economic contribution to pest control (Waage et al., 1988; Losey and Vaughan,  
331 2006).

332 Direct non-target impacts arise when applied EPN infect and kill organisms other than the target  
333 pest. Considering the wide potential host range of EPN (Peters, 1996), occasional infection of  
334 non-target individuals is probably common when inundatively applying EPN IJs, but this should  
335 be distinguished from widespread or pervasive non-target infection that reduces abundance and  
336 diversity of non-target species (Bathon, 1996; van Lenteren et al., 2003). Published surveys of  
337 non-target impacts at population and community level, before and after EPN application, suggest  
338 that such impacts are rare and, if they do occur, tend to be minor (Bathon, 1996; Hodson et al.,  
339 2002; Barratt et al., 2006). Nonetheless, plantation forests and the associated clear-fell sites,  
340 though not always as diverse as mature and natural forest stands (Grove, 2002, Irwin et al.,  
341 2014), may harbour a significant number of insects, particularly saproxylics, including red-listed  
342 species (Sippola et al., 2002; Jonsell, 2007; Irwin et al., 2014). To assess the impact of EPN on  
343 non-target insects in the pine weevil system we looked both for effects on community  
344 composition and on two key ecosystem service providers, a parasitoid and a common saproxylic  
345 species.

346 Saproxylic beetles, which develop in or feed on decomposing wood for at least part of their life  
347 cycle, are considered beneficial in forest management and are, therefore, worth protecting  
348 (Speight, 1989). These beneficial non-target insects may be at risk of infection as they occupy a  
349 similar habitat to the pine weevil. The two-banded longhorn beetle *Rhagium bifasciatum*  
350 Fabricius 1775 (Coleoptera: Cerambycidae) is an important wood-decomposing insect on clear-  
351 fell sites in Europe (Duffy, 1953; Twinn & Harding, 1999). It develops over several years in  
352 fallen deadwood and wood debris but, as tree stumps only become suitably decomposed for this  
353 species three to four years after felling (Duffy, 1953), it usually does not co-occur with pine  
354 weevils, which are present in stumps one to three years after felling (Leather et al., 1999). These  
355 longhorns may, however, be impacted by misdirected spray during nematode application or by  
356 EPN dispersing from treated stumps. Harvey et al. (2012) demonstrated that larvae, pupae and  
357 adults of *R. bifasciatum* could be infected by both *S. carpocapsae* and *H. downesi* within  
358 decomposing deadwood logs, though infection was significantly lower in field experiments than  
359 in the laboratory. High rates of infection (> 30 % of insects) were typically only observed in logs  
360 that had been directly drenched with a dose of 1.8 million IJs, half the number applied per stump  
361 for pine weevil suppression (Dillon et al., 2008a). *Rhagium bifasciatum* infected with EPN were  
362 also found in deadwood 1-12 months after application of *S. carpocapsae* to stumps on an  
363 operational, site-wide scale, but fewer than 10% of logs contained infected insects, and infected  
364 insects represented less than 4% of the overall population sampled. Both *S. carpocapsae* and *H.*  
365 *downesi* reproduced in *R. bifasciatum* larvae, so it is possible that some of the infection was as a  
366 result of recycling within the logs. The number of logs with infected *R. bifasciatum*, and number  
367 of infected longhorns per log declined significantly with increasing distance of logs from treated  
368 stumps (Harvey et al., 2012). The targeted application of EPN around tree stumps therefore

369 appears to limit direct non-target risks for this and probably also other saproxylic beetles in  
370 deadwood and wood debris.

371 *Bracon hylobii* Ratzeburg 1848 is an important beneficial insect that provides natural control of  
372 the large pine weevil (Henry & Day, 2001). Parasitism rates of pine weevil by this gregarious  
373 ectoparasitoid are typically in the range of 15 – 30 % (Dillon et al., 2008; Harvey, unpublished  
374 data), but can be as high as 90 % (Henry, 1995). Any intraguild predation of EPN on *B. hylobii*  
375 could potentially be detrimental to this natural control (Rosenheim et al., 1995). Several  
376 parasitoid wasps are susceptible to EPN, especially as larvae (Battisti, 1994; Lacey et al., 2003;  
377 Mbata & Shapiro-Ilan, 2012). Larvae, pupae and adults of *B. hylobii* were susceptible to *H.*  
378 *downesi* infection in laboratory assays (Everard et al., 2009). Adults emerging from cocoons  
379 were most susceptible (80 % mortality in close-contact trials) while pupae inside cocoons were  
380 infected only rarely (< 8 % of pupae infected inside cocoons after exposure to 10,000 IJs of *H.*  
381 *downesi* [Everard et al., 2009]). However, such close-contact laboratory assays, with high  
382 concentrations of EPN, almost certainly over-represent infection rates in the field. Dillon et al.  
383 (2008b) found no reduction in *B. hylobii* parasitism of pine weevil in stumps treated with *H.*  
384 *downesi* or *S. carpocapsae* 18 to 23 months earlier, but infection of *B. hylobii* itself with EPN  
385 was not assessed. Susceptibility of a parasitoid to EPN does not necessarily impact on parasitism  
386 of the pest: larvae of the parasitoid *Habrobracon hebetor* Say 1836 are susceptible to infection  
387 with *Heterorhabditis indica* Poinar, Karunakar & David, 1992, but when nematode and wasp  
388 were used together against Indian meal moth *Plodia interpunctella* Hübner 1813 in laboratory  
389 assays, no antagonistic effect was observed (Mbata & Shapiro-Ilan, 2012)..

390 Tree stumps can harbour a large diversity of invertebrates, both in the decomposing wood and  
391 bark, and in the soil around them (Wallace, 1953; Abrahamsson & Lindbladh, 2006; Hedgren,  
392 2007). Since this is where EPN are applied (Dillon et al., 2008a), impacts on non-target insects  
393 are most likely to occur in this area. When debarking tree stumps to record infection of pine  
394 weevil after application of EPN, infected non-target insects (e.g. Elateridae) were occasionally  
395 found (Harvey, Dillon, pers. obs.). To monitor effects of EPN on non-target Coleoptera, Dillon et  
396 al. (2012) placed insect emergence traps over stumps treated with *S. carpocapsae* or *H. downesi*  
397 and over untreated stumps. EPN did not affect species diversity, richness, abundance or  
398 community composition, either in the year of application or one year later (Dillon et al., 2012).  
399 In particular, EPN application had no significant effect on wood-associated species including the  
400 abundant saproxylic cerambycid, *Asemum striatum* L. 1758 (Dillon et al., 2012). The authors  
401 concluded that the impact on non-target Coleoptera in and around tree stumps is probably  
402 negligible for the two species tested to date.

403 Based on the available data summarized here, direct non-target impacts of the EPN species  
404 investigated are ‘unlikely’ when applied against pine weevil (likelihood = 2; Hickson, 2000; van  
405 Lenteren et al., 2003) (Table 2). In addition, data for both wood debris-associated and stump-  
406 associated non-target insects suggest mortality of these insects is < 5 % of the total available  
407 non-target population on site (magnitude = 1; van Lenteren et al., 2003). These assessments,  
408 while supported by the limited data available for some EPN species, should be considered  
409 tentative until further experimental data become available, especially for species whose non-  
410 target risks have not yet been studied in detail in forest ecosystems.

411

412 e) Indirect non-target effects

413 Indirect effects of biological control are among the most difficult to study and disentangle  
414 (Simberloff, 2012), making them the least researched aspect of risk assessment. Applying large  
415 numbers of EPN may influence trophic interactions in the soil, thereby potentially changing  
416 nematode (Somasekhar et al., 2002) and/or microarthropod assemblages (Hodson et al., 2002) as  
417 well as nutrient cycles (De Nardo et al., 2006). Where persistence and dispersal of a control  
418 agent are low risk factors, it can be argued that indirect non-target effects are also unlikely  
419 (Barratt et al., 2006). Nonetheless, they should be assessed, for completeness. EPN may compete  
420 for hosts with other parasites, pathogens and parasitoids at the same trophic level. In the pine  
421 weevil system, we consider indirect effects on native EPN and on *Bracon hylobii*. Studies  
422 elsewhere indicate that endemic nematodes may persist in spite of inundative application of EPN  
423 (Miller and Barbercheck, 2001; Duncan et al., 2003). For example, Millar and Barbercheck  
424 (2001) tested whether indigenous *S. carpocapsae* and *H. bacteriophora* were displaced by the  
425 exotic nematode *Steinernema riobrave* (Cabanillas, Poinar, and Raulston, 1994) after inundative  
426 application to corn fields in the US. Though the exotics persisted for more than two years, no  
427 evidence of long-term displacement of either of the endemic species was found (Millar &  
428 Barbercheck 2001). *Steinernema feltiae* was the only EPN recovered in a survey of coniferous  
429 forestry throughout Ireland, being found in 10% of mature standing forests and 7% of replanted  
430 clear-felled sites (Dillon, 2003), though *S. kraussei* has also been detected (Harvey,  
431 unpublished). While *S. carpocapsae* was detected for at least 2 years following application, it  
432 was replaced on several sites by indigenous steinernematids (Harvey and Griffin, 2016). As the  
433 sites had not been sampled for EPN prior to treatment, it is not known whether endemic EPN  
434 were temporarily suppressed to undetectable levels, or their later detection was as a result of a

435 new colonisation of the sites. Dillon et al. (2008a) found that the exotic species *S. carpocapsae*  
436 and *H. downesi* and the exotic strain *S. feltiae* EN02 did not displace native strain *S. feltiae*  
437 4CFMO on Irish clear-fell sites treated for pine weevil control. When applying an exotic strain of  
438 an indigenous species, there is a risk of introgression (Roderick & Navajas, 2003; Hopper et al.,  
439 2006), but there was no evidence of hybridization between indigenous and applied strains of *S.*  
440 *feltiae* (Dillon et al., 2008a). These findings suggest that indigenous EPN species are unlikely to  
441 be displaced in the long term by exotics that are not adapted to the target environment (Grewal et  
442 al., 1994), but tests on further EPN species that may be used in pine weevil suppression activities  
443 should be considered as the next step in the assessment of indirect non-target effects.

444 As previously noted, inundatively applied EPN may have direct effects on the parasitoid *B.*  
445 *hylobii* by killing various life stages. We also consider the possibility of competition between  
446 nematodes and this parasitoid for pine weevil larvae. *Bracon hylobii* cannot develop to adulthood  
447 on hosts that have been infected with EPN; females oviposited on healthy host larvae, but not on  
448 larvae killed by *H. downesi* or *S. carpocapsae*, which should reduce the negative impact on the  
449 parasitoid (Everard et al., 2009; Harvey & Griffin, 2012). Female *B. hylobii*, especially those  
450 with prior experience, did parasitize live hosts infected with EPN, as long as they were still  
451 moving (Everard et al., 2009; Harvey & Griffin, 2012). While this means there is a possibility of  
452 competition between EPN and *B. hylobii* (modulated by wasp experience), complementary  
453 (additive or synergistic) control effects by the two agents may also emerge (Harvey & Griffin,  
454 2012). Dillon et al. (2008b) reported an additive effect of *H. downesi* and *S. carpocapsae* with *B.*  
455 *hylobii* on mortality of pine weevil in stumps across three sites. Larger-scale and longer-term  
456 monitoring of *B. hylobii* populations is necessary to draw more definite conclusions about  
457 population-scale effects of competition between EPN and *B. hylobii*.

458 We estimate that indirect non-target effects of exotic EPN species and strains used for large pine  
459 weevil control (i.e. *S. carpocapsae*, *S. feltiae* EN02 and *H. downesi*) are ‘unlikely’ (likelihood =  
460 2; Hickson, 2000; van Lenteren et al., 2003) (Table 2), and we expect these exotics to have only  
461 a ‘minor’ impact on non-target organisms (magnitude = 2; van Lenteren et al., 2003) (Table 2).  
462 Furthermore, we consider indirect non-target impacts to be ‘very unlikely’ for the native *S.*  
463 *feltiae* 4CFMO (likelihood = 1; Hickson, 2000; van Lenteren et al., 2003) as it is already a  
464 natural component of coniferous forest soils in Ireland and thus inundative application should not  
465 have a qualitative impact on the soil organism community. It should be stressed, however, that  
466 these assessments are based on the different aspects of indirect non-target impact investigated for  
467 each of the species and that results for one species are not necessarily representative of others.  
468 While we have not included exact risk values for *H. megidis* and *S. kraussei*, the other two  
469 species that have been tested against pine weevil and for which fewer data are available, we  
470 estimate *H. megidis* to be similar to its close relative *H. downesi*, both being exotic to the habitat,  
471 and *S. kraussei* to be similar to *S. feltiae*, both species being present in the target habitat.

472

### 473 Conclusions and risk evaluation

474 Both exotic and indigenous EPN trialled against the large pine weevil persisted in the soil for up  
475 to four years after application (Dillon et al., 2008a; Harvey & Griffin, 2016), but the evidence  
476 suggests that persistence was driven by recycling through the target pest as intended.  
477 Consequently, EPN levels decreased to background levels (for an indigenous strain) or  
478 undetectable levels (for exotic species/strains) along with the natural decrease in pest population  
479 (Torr et al., 2007; Dillon et al., 2008a; Harvey & Griffin, 2016). Moreover, the exotic applied

480 strain of *S. feltiae* did not displace an indigenous strain (Dillon et al., 2008a). Active horizontal  
481 dispersal appeared to be limited to a zone of less than 1 m from the point of application and,  
482 while phoresis or some other long-range mechanism of dispersal resulted in movement of EPN  
483 outside the treated areas, there is no evidence that they established there (Dillon et al., 2008a;  
484 Harvey & Griffin, 2016). Direct non-target effects are limited by the targeted application of  
485 exotic EPN (Harvey et al., 2012) and coleopteran communities around tree stumps were  
486 unaffected by exotic EPN (Dillon et al., 2012). Moreover, while the parasitoid *B. hylobii* is  
487 susceptible to infection by and competition with EPN, there is no indication that this negatively  
488 impacts on *B. hylobii* parasitism in the field (Dillon et al., 2008b; Everard et al., 2009; Harvey &  
489 Griffin, 2012). Thus, both exotic and indigenous EPN seem to be well-suited as a low-risk  
490 alternative to chemical pesticides. While most of the risk assessment studies carried out in our  
491 target forest ecosystem focussed on just two species, *S. carpocapsae* and *H. downesi*, we have  
492 extrapolated our conclusions to *S. feltiae*. We feel this is acceptable, as *S. feltiae* as the species  
493 indigenous to the system can be considered a priori of low risk.

494 Current risk considerations and regulatory restrictions on exotics have resulted in a trend to  
495 favour indigenous inundative control agents over exotic ones, reversing the past emphasis on use  
496 of exotics (van Lenteren, 2012). The results presented here do not suggest that risk, as defined by  
497 van Lenteren et al. (2003), is increased by using exotic species. In fact, using EPN that are not  
498 well-adapted to the environment where they are applied might reduce the risk of long-term  
499 establishment (Grewal et al., 1994). The indexing method devised by van Lenteren et al. (2003),  
500 when applied strictly, is only valid for the environment and setting in which the risk for the  
501 control agent has been evaluated. In the setting of large pine weevil control using EPN, we  
502 estimate the risk index of the exotic *H. downesi* and *S. carpocapsae* to be 35, as also for the

503 exotic strain of *S. feltiae*, EN02 (Table 2). We arrived at a somewhat higher index value of 51 for  
504 *S. feltiae* 4CFMO (native) in a forestry setting in Ireland (Table 2). The main risk category  
505 contributing to the differences in indices is establishment; we assign higher scores to the native  
506 Irish species *S. feltiae*, particularly the native strain 4CFMO, as it has the potential to persist for  
507 longer in coniferous clear-fell soils after application (Dillon et al. 2008a). However, since this  
508 species already occurs naturally in this ecosystem, in this case a higher risk index value does not  
509 necessarily imply a greater environmental hazard due to application. If we take the establishment  
510 risk of *S. feltiae* to be the less conservative 1, then its index value becomes 36. By comparison,  
511 van Lenteren et al. (2003) assign an index value of 53 to *S. feltiae* when released in Finland  
512 (where it is indigenous) in an open field environment. The slightly different indices between the  
513 two studies for application of a native *S. feltiae* are accounted for by higher estimates for  
514 establishment and dispersal, and lower estimates for direct and indirect non-target effects in our  
515 system compared to that of van Lenteren et al.

516 Of course, no risk assessment can ever be complete and offer a guarantee of safety – risks and  
517 benefits must therefore always be weighed in sensible proportion to each other (Clerq et al.,  
518 2011; Simberloff, 2012). The pine weevil has been controlled in Ireland and elsewhere mainly by  
519 applying chemical pesticide (most recently cypermethrin or  $\alpha$ -cypermethrin) to replanted  
520 seedlings before and/or after planting (e.g. Torstensson et al., 1999; Willoughby et al., 2004).  
521 EPN, as part of an integrated pest management strategy, are intended to help replace  
522 cypermethrin and  $\alpha$ -cypermethrin as their use is phased out in the European Union under  
523 sustainable forest management (SFM) policies. An extensive body of research investigating  
524 environmental impacts of pyrethroid pesticides in forestry shows that they can affect a much  
525 wider range of organisms than do EPN (e.g. crustaceans and vertebrates), can impact on

526 terrestrial and – unlike EPN – also aquatic non-target organisms and can persist in both soil and  
527 freshwater (e.g. McLeesc et al., 1980; Anderson, 1982; Kreutzweiser & Kingsbury, 1987;  
528 DeLorenzo and Fulton, 2012). Moreover, by altering the composition of freshwater invertebrate  
529 communities, pyrethroids can also have indirect impact on other non-target organisms  
530 (Kingsbury & Kreutzweiser, 1987). Though the risk indexing method by van Lenteren et al.  
531 (2003) is not designed to incorporate chemical pesticides, the risk of pyrethroids in terms of host  
532 range, persistence (analogous to establishment for EPN) and direct and indirect non-target  
533 impacts in the context of pine weevil control is likely to be greater than that of the EPN  
534 discussed here. This is consistent with Laengle & Strasser (2010), who compared risk factors for  
535 biological control agents with pesticides. They report risk factors in the order of thousands for  
536 pesticides and in the order of hundreds for biological control agents. Thus, from the perspective  
537 of minimizing the risk of environmental impact, EPN appear to be a superior alternative to  
538 conventional chemical control methods when managing the large pine weevil.

539

540 **Acknowledgments:** CDH was funded by the EPA STRIVE programme (project 2007-PhD-B-6)  
541 and CDW was funded by INTERREG IVA (IMPACT Project), co-funded by the Department of  
542 Agriculture, Food and the Marine (DAFM). Field trials were conducted under licence from the  
543 Pesticide Control Service of DAFM.

544

545 Table 1: EPN species and strains for which risk assessment studies have been carried out in  
 546 relation to pine weevil suppression. For each species and strain, status (exotic or indigenous) is  
 547 given for Britain (Br) and Ireland (Irl) in general, and coniferous forest soils in these islands in  
 548 particular. Risk categories after van Lenteren et al. (2003) are E = establishment, D = dispersal,  
 549 DNT = direct non-target effects and INT = indirect non-target effects.

550

EPN species	Strain and origin	Species/strain present in Br/Irl <sup>1</sup>	Species/strain present in coniferous forest soils? <sup>1</sup>	Risk categories Evaluated <sup>1</sup>
Steinernema carpocapsae	All strain, USA	<b>No</b> (1,2,3,5,7,8,11,12)	<b>N/A</b>	<b>E, D, DNT, INT</b> 15,16,18,19,20, 21
Steinernema feltiae	4CFMO, Ireland	<b>Yes</b> (1,4,5,7,8,11,12)	<b>Yes</b> (2, 12, 13)	<b>E, D, INT</b> 15
Steinernema feltiae	EN02, Germany	<b>Yes<sup>2</sup></b> (1,4,5,7,8,11,12,15)	<b>No<sup>2</sup></b> (15)	<b>E, D, INT</b> 15
Steinernema kraussei	Not specified (Torr et al. 2007)	<b>Yes</b> (7,8,11,13)	<b>Yes</b> (8,13)	<b>E</b> 14
Heterorhabditis downesi	K122, Ireland	<b>Yes</b> (6,11)	<b>No</b> (2,4,8,12)	<b>E, D, DNT, INT</b> 15,16,17,18,19, 20
Heterorhabditis megidis	UK211, UK; NL-HF85, Netherlands	<b>Yes<sup>3</sup></b> (7,11)	<b>No</b> (2,4,8,12)	<b>E, D, INT</b> 15

570 Table 2: Risk indices for *Steinernema carpocapsae*, *Heterorhabditis downesi* and *Steinernema*  
571 *feltiae* when used against the large pine weevil. Values for likelihood of risk are determined on a  
572 scale of 1 to 5 (1 = very unlikely, 2 = unlikely, 3 = possible, 4 = likely, 5 = very likely), as are  
573 values for magnitude (1 = minimal, 2 = minor, 3 = moderate, 4 = major, 5 = massive), based on  
574 criteria outlined in van Lenteren et al. (2003). Within each risk category, the values for  
575 likelihood and magnitude of effects are multiplied, and the products are added to give the risk  
576 index (van Lenteren et al. 2003).

EPN species/strain		Risk category					Risk index
		Establishment	Dispersal	Host range	Direct non-target effects	Indirect non-target effects	
<i>S. carpocapsae</i>	Likelihood	2	2	5	2	2	<b>35</b>
	Magnitude	1	1	5	1	2	
	<b>L x M</b>	<b>2</b>	<b>2</b>	<b>25</b>	<b>2</b>	<b>4</b>	
<i>H. downesi</i>	Likelihood	2	2	5	2	2	<b>35</b>
	Magnitude	1	1	5	1	2	
	<b>L x M</b>	<b>2</b>	<b>2</b>	<b>25</b>	<b>2</b>	<b>4</b>	
<i>S. feltiae</i> (EN02)	Likelihood	2	2	5	2	1	<b>35</b>
	Magnitude	2	1	5	1	2	
	<b>L x M</b>	<b>4</b>	<b>2</b>	<b>25</b>	<b>2</b>	<b>2</b>	
<i>S. feltiae</i> (4CFMO)	Likelihood	4	2	5	2	1	<b>51</b>
	Magnitude	5	1	5	1	2	
	<b>L x M</b>	<b>20</b>	<b>2</b>	<b>25</b>	<b>2</b>	<b>2</b>	
<i>S. feltiae</i> <sup>1</sup>	Likelihood	3	1	5	4	4	<b>53</b>
	Magnitude	5	1	5	2	1	
	<b>L x M</b>	<b>15</b>	<b>1</b>	<b>25</b>	<b>8</b>	<b>4</b>	

577  
578 <sup>1</sup> The risk index for *S. feltiae* when applied to an open field in Finland from van Lenteren et al.  
579 (2003) is given here for comparison.
