## **Abstract**

We compared coincidence-anticipation performance in normal vision and stroboscopic vision as a function of time-on-task. Participants estimated the arrival time of a real object that moved with constant acceleration (-0.7, 0, +0.7 m/s<sup>2</sup>) in a pseudo-randomised order across 4 blocks of 30 trials in both vision conditions, received in a counter-balanced order. Participants (n=20) became more errorful (accuracy and variability) in the normal vision condition as a function of time-on-task, whereas performance was maintained in the stroboscopic vision condition. We interpret these data as showing that participants failed to maintain coincidence-anticipation performance in the normal vision condition due to monotony and attentional underload. In contrast, the stroboscopic vision condition placed a greater demand on visual-spatial memory for motion extrapolation, and thus participants did not experience the typical vigilance decrement in performance. While short-term adaptation effects from practicing in stroboscopic vision are promising, future work needs to consider for how long participants can maintain effortful processing, and whether there are negative carry-over effects from cognitive fatigue when transferring to normal vision.

**Keywords:** Coincidence-anticipation, Stroboscopic Vision, Attention, Vigilance.

## 1 **Introduction**

2           The human visual system typically receives an intermittent flow of incoming  
3 information due to blinks, saccades and periods of transient occlusion when an object-of-  
4 interest disappears from view behind another object or surface (e.g., as the ball is obscured by  
5 the defensive players during a free kick in soccer). This usually goes unnoticed, with the  
6 intermittent input transformed into a unified and continuous perceptual experience. However,  
7 even when there are longer periods of occlusion (e.g., artificial manipulation using stroboscopic  
8 vision eyewear), relevant information can be gained from intermittent visual samples to provide  
9 sufficient information for successful performance of precision interceptive actions<sup>1</sup>. Recently,  
10 it has been reported that practicing in such vision conditions can facilitate sports-specific skills  
11 in ice-hockey<sup>2</sup> and baseball<sup>3</sup>. Analogous to altitude training for the endurance athlete<sup>4</sup>, the  
12 premise is that practicing in stroboscopic vision encourages visual-cognitive processes to adapt  
13 in order to cope with the suboptimal information available. Processes shown to transfer  
14 positively when vision is subsequently restored to normal include short-term visual memory<sup>5</sup>,  
15 coincidence-anticipation timing<sup>6</sup>, and motion coherence and attention in central vision<sup>7</sup>.

16           Continuing with the analogy of altitude training, it follows that practicing in  
17 stroboscopic vision is effortful and attentionally demanding. Indeed, anecdotal reports suggest  
18 that participants exhibit more focussed attention on an approaching object when practicing  
19 catching tasks in stroboscopic vision<sup>8</sup>. This is consistent with related empirical work that has  
20 shown an overall increase in attention (i.e., “high-beams” effect) in order to maintain a  
21 persistent visual-spatial memory of relevant stimulus locations (i.e., object and distractors)  
22 when vision is intermittently occluded<sup>9</sup>. It is important to recognize, however, that a high  
23 attentional load and effortful processing cannot be maintained indefinitely. In accord with the  
24 overload hypothesis<sup>10</sup>, it follows that a high attentional load can eventually lead to the depletion  
25 of attentional resources and a decrement in performance. This has implications for the design

1 of stroboscopic vision training programmes, which to date have used both experimenter-  
2 determined (e.g., 25 minutes<sup>5</sup>, 5-7 minutes<sup>6</sup>, and self-determined (e.g., 10-45 minutes<sup>2</sup>)  
3 exposure duration.

4 In the current study we sought to determine the effect of stroboscopic vision on  
5 attentional allocation while performing coincidence-anticipation timing, which is a key  
6 element to many daily life activities such as driving or in different sporting disciplines where  
7 it is necessary to avoid or intercept moving objects<sup>11</sup>. Rather than using a probe-reaction  
8 procedure to determine the amount of attention used when performing coincidence-anticipation  
9 timing in stroboscopic vision compared to normal vision, we were interested to know if  
10 stroboscopic vision influences the ability to sustain attention as a function of time-on-task.  
11 Therefore, we adopted the method used for testing psychomotor vigilance, whereby  
12 participants are required to sustain attention over time in order to respond efficiently to repeated  
13 presentation of the imperative stimulus<sup>12</sup>. Specifically, we compared vigilance in a normal  
14 vision condition and a stroboscopic vision condition (4Hz) while performing repeated trials of  
15 a coincidence-anticipation task in which the object moved with constant acceleration (-0.7, 0,  
16 +0.7 m/s<sup>2</sup>). We hypothesised that participants would exhibit deterioration in performance  
17 (accuracy and variability) as a function of time-on-task in the normal vision condition due to  
18 monotony and attentional underload<sup>13</sup>. Conversely, we hypothesised that the greater demand  
19 on visual-spatial memory for motion extrapolation in the stroboscopic vision condition would  
20 enable participants to sustain attention and thus offset the typical vigilance decrement.

21

## 22 **Methods**

### 23 *Participants*

24 Twenty male undergraduate students ( $M = 23.15$  years of age,  $SD = 2.35$ ) volunteered  
25 to take part in the study. All participants reported having normal or corrected-to-normal vision.

1 Participants were provided with general information about the task and stimulus prior to giving  
2 informed written consent. All procedures were conducted in accordance with the Declaration  
3 of Helsinki and were approved by the Liverpool John Moores University Research Ethics  
4 Committee.

#### 5 *Apparatus, Task and Procedure*

6 *Coincidence-Anticipation:* Participants were required to press a button mounted in a  
7 hand-held joystick at the moment an object (single red LED of 5mm diameter) that moved  
8 along a 3m linear track (HEPCO) reached a fixed target position. The target comprised two red  
9 LEDs (5mm diameter) mounted on either side of the track. The object was attached to a sled  
10 that was moved along the linear track by a stepper motor controlled by in-house routines  
11 implemented in MATLAB (The Mathworks, Inc., MA, USA). The object moved with constant  
12 acceleration ( $-0.7, 0, +0.7 \text{ m/s}^2$ ) such that it reached the target after 1000ms moving with a  
13 velocity of 1.25m/s. It then continued to move with the same acceleration for a further 100ms,  
14 after which it was brought to a standstill. The target remained stationary for 2000ms, and then  
15 moved slowly back to the start position for the next trial. The moment the button was pressed  
16 and the sled reached a switch located coincident with the target were recorded via a data  
17 acquisition card (NI PCI-6035E) and stored for offline analysis.

18 Participants performed the coincidence-anticipation task in a normal vision condition and  
19 stroboscopic vision condition. In the latter, participants wore eyewear (Nike Vapor Strobe®)  
20 with LCD lenses that cycled between “open” and “closed” states. The “open” state had a fixed  
21 duration of 100ms, whereas the “closed” state could be set at one of eight levels. Following  
22 previous work on stroboscopic vision during coincidence-anticipation<sup>6</sup>, here we selected level  
23 3 for the closed state, which had a duration of 150ms (i.e., 4Hz cycling rate). In the “closed”  
24 state the lenses are less transparent and thereby are likely to perturb perception of motion and  
25 form (see discussion). Effectively, in the “closed” state the lenses act as neutral density filters

1 and thus reduce light transmission. Under ambient room lighting (625 lux), which was used  
2 throughout experimental testing, a digital light meter (Lutron LX-1108, Taipei, Taiwan)  
3 located directly behind the lens of the stroboscopic vision eyewear indicated the illuminance  
4 was 128 lux in the “closed” state. An illuminance of 100 lux is similar to that of a “very dark  
5 overcast day”<sup>14</sup>, while 320 lux is the minimum illuminance for office lighting recommended  
6 by the US Department of Labour. We were unable to reliably measure illuminance when the  
7 stroboscopic eyewear were in the “open” state (100ms), although the lenses were sufficiently  
8 transparent that participants reported having normal visibility. To ensure that participants in  
9 the normal vision condition believed they were the subject of an intervention, and thus  
10 experienced similar expectation effects as the stroboscopic vision condition (i.e., Hawthorne  
11 and/or placebo effect), they performed the coincidence-anticipation task while wearing a pair  
12 of NVIDIA LCD shutter glasses (Expressway Santa Clara, CA, USA). These were not switched  
13 on and connected to a 3D graphics card, and thus permitted light transmission of 239 lux. While  
14 illuminance was reduced compared to that of ambient lighting, participants reported having an  
15 uninterrupted view of the moving object during the coincidence-anticipation task.

16 Prior to the commencing experimental testing, the experimenter explained the procedure  
17 and provided the participant with the necessary eyewear. Half of the participants performed the  
18 coincidence-anticipation task in the stroboscopic vision condition followed by the normal  
19 vision condition, whereas the other half performed the normal vision condition followed by the  
20 stroboscopic vision condition. The participant next performed 10 familiarization trials,  
21 followed by 4 blocks of 30 experimental trials. Within each block, the level of acceleration was  
22 pseudo-randomly ordered to encourage participants to use the available visual information (e.g.,  
23 not respond at a fixed distance) and to minimize boredom associated with repeated attempts  
24 with the same motion. To prevent a learning effect with respect to acceleration that could have  
25 influenced allocation of attention, knowledge of results on coincidence-anticipation accuracy

1 was not communicated to the participant. The duration to complete each vision condition was  
2 between ten and eleven minutes depending on the participant's response time to each trial, and  
3 was thus similar to previous studies that have shown a vigilance decrement when completing  
4 a computer-based reaction time (RT) task (see below) for an extended number of trials without  
5 a break.

6 *Psychomotor Vigilance:* Between completing the coincidence-anticipation task in the  
7 normal vision and stroboscopic vision conditions, participants performed a computer-based  
8 psychomotor vigilance task (PVT). The presentation of stimuli, timing operation, and  
9 collection of responses was controlled by E-Prime software (Psychology Software Tools,  
10 Pittsburgh, PA, USA) running on a desktop computer (Dell OptiPlex). The PVT required  
11 participants to respond, as rapidly as possible, to a visual stimulus that appeared on a computer  
12 monitor located 50cm from where they were seated. During each trial of the PVT, a Gabor  
13 patch ( $4.20^\circ \times 4.20^\circ$ ) was presented with a horizontal orientation against a grey background at  
14 the center of the screen. Then, after a random time interval between 2000ms and 10000ms, the  
15 orientation of the Gabor patch was abruptly switched to vertical (see Figure 1). Participants  
16 were instructed to respond to this change of orientation as quickly as possible by pressing the  
17 space bar on a keyboard (Razr Lycosa, 1000Hz polling) with the index finger of their dominant  
18 hand. Feedback of the response time was displayed on the screen after each trial during a 300ms  
19 inter-trial interval. If no response was given within 5000ms of changing the orientation of the  
20 Gabor patch, the message "You did not answer" appeared on the screen and the next trial began.  
21 The PVT lasted for 9 minutes without interruptions and is accepted to provide a simple and  
22 reliable measure of vigilance given the monotonous, repetitive, and unpredictable nature of the  
23 target onset<sup>15</sup>. It has been reported that failures (e.g., slowing of RT or increase in lapses) in  
24 vigilance performance in the PVT can occur within 5 minutes in adults<sup>15,16</sup>, and even shorter  
25 duration in adolescents and children<sup>17,18,19</sup> However, we decided to follow the original

1 developers' recommendation of a 9 minute PVT<sup>20</sup>, which also approximated the duration of  
2 coincidence-anticipation task and thus permitted between-task comparison.

### 3 *Data Analysis*

4 *Coincidence-Anticipation:* We first calculated the signed error on each trial between  
5 button press and object arrival at the target. Response with an absolute value of >300ms were  
6 classified as outliers and removed (< 1.0%) from additional analyses<sup>11</sup>. From the remaining  
7 trials, we calculated intra-participant mean constant error (accuracy) and variable error  
8 (variability) for each level of object acceleration in each of the four blocks. The intra-  
9 participant mean data were submitted to separate 2 Vision (normal, stroboscopic) x 3  
10 Acceleration (-0.7, 0, +0.7 m/s<sup>2</sup>) by 4 Block (1, 2, 3, 4) repeated measures ANOVA. In cases  
11 where Mauchley's sphericity test was significant, Greenhouse-Geisser corrections were  
12 applied. Tukey's Honestly Significant Difference (HSD) tests were then used to determine the  
13 origin of any significant main and interaction effects.

14 *Psychomotor Vigilance:* Intra-participant mean (accuracy) and standard deviation  
15 (variability) of RT was calculated for consecutive 3 minute intervals of the 9 minute total task  
16 duration. Trials with RT below 100 ms (< 1.0%) were considered to be anticipation errors and  
17 therefore discarded from the analysis<sup>15</sup>. The intra-participant mean and standard deviation data  
18 of RT submitted to a one-way ANOVA with Block (1, 2, 3) as a repeated measure. Tukey HSD  
19 post-hoc tests were used to investigate the significant main effect.

20

## 21 **Results**

### 22 *Coincidence-Anticipation*

23 For constant error there was a significant main effect of Acceleration,  $F(1.26, 24.03) =$   
24  $56.62, p < .001, \eta^2_{\text{partial}} = .75$ . Participants exhibited greater underestimation of object arrival  
25 when it decelerated (-117ms) compared to when it had constant velocity (-101ms) or

1 accelerated (-78ms),  $p < .001$ . There was no main effect of Block,  $F(3,57) = 2.47$ ,  $p = .07$ ,  
2  $\eta^2_{\text{partial}} = .12$ , or Vision,  $F(1,19) = 1.94$ ,  $p = .18$ ,  $\eta^2_{\text{partial}} = .08$ , but there was a significant  
3 interaction between these factors,  $F(2.02,38.36) = 5.28$ ,  $p = .008$ ,  $\eta^2_{\text{partial}} = .22$ . Participants  
4 became less accurate in the normal vision condition across the 4 blocks, whereas they  
5 maintained a similar level of accuracy in the strobe vision condition. As shown in Figure 2,  
6 constant error in the normal vision condition deteriorated from block 1 (-85 ms) to block 3 (-  
7 101 ms),  $p = .04$ , and block 4 (-103ms),  $p < .01$ . As a consequence, while constant error was  
8 significantly less in the normal vision than strobe vision condition in blocks 1, there was no  
9 difference in constant error for the remaining blocks. Observation of the individual participants'  
10 data revealed that 16 of 20 exhibited an increase in constant error between block 1 and 4 in the  
11 normal vision condition. In the strobe vision condition, an increase in error was evident in 9 of  
12 20 participants.

13 For variable error there was a significant main effect of Acceleration,  $F(2,38) = 10.62$ ,  
14  $p < .001$ ,  $\eta^2_{\text{partial}} = .36$ . Participants were more variable when the object decelerated (45ms)  
15 compared to when it moved with constant velocity (40ms) or accelerated (38ms), both  $p < .05$ .  
16 There was also a significant main effect of Vision,  $F(1,19) = 64.68$ ,  $p < .001$ ,  $\eta^2_{\text{partial}} = .77$ ,  
17 but this was superseded by a significant interaction between Vision and Block,  $F(3,57) = 3.04$ ,  
18  $p = .04$ ,  $\eta^2_{\text{partial}} = .14$ . As shown in Figure 3, participants became more variable in the normal  
19 vision condition across the 4 blocks, whereas they maintained a similar level of variable error  
20 in the stroboscopic vision condition. As a consequence, the initial difference in variable error  
21 between the normal vision and stroboscopic vision conditions at block 1 ( $p < .01$ ) and block 2  
22 ( $p < .03$ ) was no longer present at block 3 and block 4 ( $p > .50$ ). Observation of the individual  
23 participant data revealed that 15 of 20 exhibited an increase in variable error between block 1  
24 and 4 in the normal vision condition. In the strobe vision condition, an increase in variable  
25 error was evident in 7 of 20 participants.

1 Additional analyses were conducted to determine if the change (between blocks 1 and  
2 4) in mean and variability of coincidence-anticipation were related. This indicated no  
3 significant correlation in either normal vision,  $r(20) = 0.15, p = .54$ ) or stroboscopic vision,  
4  $r(20) = 0.40, p = .08$ ). Notably, however, observation of the individual participant data revealed  
5 that 12 of the 20 became both less accurate and more variable in the normal vision condition.  
6 Only 1 participant became more accurate and less variable in the normal vision condition. The  
7 pattern was reversed in the stroboscopic vision condition, where 10 participants became more  
8 accurate and less variable. Of the remaining 10 participants, 6 became both less accurate and  
9 more variable.

#### 10 *Psychomotor Vigilance Task*

11 The analysis of the participants' mean RT revealed a significant main effect of Block,  
12  $F(2,38) = 6.99, p = .003, \eta^2_{\text{partial}} = .27$ . Tukey HSD post-hoc tests indicated a significant  
13 difference between block 1 (268 ms) and block 3 (289 ms),  $p = .002$ . There was no main effect  
14 of Block on participants' variability in RT,  $F(2,38) = 0.38, p > .68, \eta^2_{\text{partial}} = .02$ . Group mean  
15 variability was 61, 53 and 67 ms, respectively. Additional analyses on the change in mean and  
16 variability of PVT indicated a significant relationship,  $r(20) = 0.59, p = .006$ . Observation of  
17 the individual participant data revealed that 9 of the 20 exhibited an increase in both mean and  
18 variability of RT. Only 3 participants reduced the mean and variability of RT between block 1  
19 and block 3.

20 Finally, a generalised linear model with a poisson link function indicated the number  
21 of lapses was not influenced by Block (Wald Chi-Square = 1.37,  $p = .50$ ), and thus did not  
22 provide a better fit of the data than the intercept-only model (Likelihood Ratio Chi-Square =  
23 1.48,  $p = .48$ ).

24

25

## 1 *Task Specificity*

2 Pearson product-moment correlations were calculated to determine if there was a  
3 relationship between the change in performance (i.e., last block - first block) of coincidence-  
4 anticipation and PVT. There was no significant correlation between change in constant error  
5 and mean RT in the either normal,  $r(20) = -.32$ ,  $p = .18$ , or stroboscopic vision,  $r(20) = -.03$ ,  $p$   
6  $= .90$ . Still, observation of the individual participant data revealed that 13 of the 20 did in fact  
7 exhibit deterioration in constant error in the normal vision condition and an increase in RT.  
8 There was no significant correlation between change in variability of coincidence-anticipation  
9 and PVT in either normal,  $r(20) = .23$ ,  $p = .34$ , or stroboscopic vision,  $r(20) = -.90$ ,  $p = .71$ .

## 10 11 **Discussion**

12 It has recently been reported that practice under stroboscopic vision conditions can  
13 facilitate the development of sport-specific skill<sup>2,21</sup>, and that this could be explained in part by  
14 adaptation of processes such as motion coherence and attention in central vision<sup>7</sup> and visual-  
15 spatial memory<sup>5</sup>. Central to this adaptation is the premise that practice in stroboscopic vision  
16 is effortful and demanding<sup>20</sup>. For instance, it has been reported that contrast sensitivity, which  
17 is important for form perception, is impaired at low levels of luminance<sup>22</sup>, and that thresholds  
18 for coherent motion (translational) and heading direction (radial) increase as luminance levels  
19 decrease<sup>23</sup>. Indeed, it is known that tracking a moving object relative to the surrounds in  
20 stroboscopic vision is an attentionally demanding task<sup>9</sup>, which likely engages areas in pre-  
21 frontal cortex associated with working memory for trajectory extrapolation<sup>24</sup>. In the current  
22 study, we adapted a method used to study psychomotor vigilance<sup>12,20</sup>, in order to determine if  
23 stroboscopic vision influences the ability to sustain attention to response accurately while  
24 performing a coincidence-anticipation task.

1           We found that the group of participants became less accurate and more variable in their  
2 coincidence-anticipation response in the normal vision condition as a function of time-on-task.  
3 Conversely, accuracy and variability were maintained a similar level in the stroboscopic vision  
4 condition. Consequently, differences in accuracy and variability that existed between normal  
5 vision and stroboscopic vision conditions during the first block of 30 trials were no longer  
6 evident during the last block of 30 trials. Consistent with explanations of the vigilance  
7 decrement, we interpret these data as showing that participants failed to sustain attention after  
8 repeated trials due to the monotony and relatively simple demands of coincidence-anticipation  
9 performed in normal vision (i.e., underload hypothesis<sup>13</sup>). At the level of individual participants,  
10 this was reflected in approximately two-thirds exhibiting deterioration in both accuracy and  
11 variability in the normal vision condition. Such a change in behaviour would not be expected  
12 if participants had developed a systematic bias (i.e., underestimation or overestimation) in their  
13 anticipation of object arrival time as a function of block.

14           In contrast, in the stroboscopic vision condition where there was a greater demand on  
15 visual-spatial memory for trajectory extrapolation, it would seem that participants were better  
16 able to sustain attention, and thus maintain performance over time. Indeed, there was evidence  
17 that some participants improved accuracy (n = 13) and variability (n = 11) across blocks in  
18 stroboscopic vision. For half of the participants there was a concurrent change in accuracy and  
19 variability that was consistent with a systematic improvement in anticipation of object arrival  
20 time. Importantly, this positive adaptation would not be expected had participants disengaged  
21 from the task due to high levels of boredom or fatigue. That is not to suggest, however, that  
22 coincidence-anticipation performance would be maintained indefinitely in the stroboscopic  
23 vision condition, and by all participants. Rather, in accord with the overload hypothesis<sup>10</sup>, it  
24 follows that a high attentional load and effortful processing cannot be maintained, thus

1 eventually leading to the depletion of attentional resources and subsequently a vigilance  
2 decrement in performance.

3         An important consideration in previous work regarding the benefit of stroboscopic  
4 vision training has been the potential influence of motivational and expectancy effects such as  
5 placebo or Hawthorne<sup>25</sup>. In the current study, we were careful to include additional  
6 experimental control to ensure that any change in coincidence-anticipation was not simply a  
7 result of expectancy. In particular, given the use of novel eyewear for both the stroboscopic  
8 vision and normal vision conditions, there is no reason to believe that participants would have  
9 associated a particular eyewear with a treatment or control condition and thus modified their  
10 response accordingly. Also, we did not provide participants with knowledge of results, thus  
11 minimizing motivational effects of learning. This was important because there could have been  
12 asymmetrical motivational effects if participants were better able to use the knowledge of  
13 results in the normal vision condition to reduce response error to very low levels (e.g., 0-30ms  
14 constant error previously reported<sup>11</sup>). Another important control was to present a real moving  
15 object rather than an apparent motion stimulus (e.g., Bassin-Anticipation timer). The idea was  
16 to minimize the possibility of asynchrony between the open state of the stroboscopic eyewear  
17 and presentation of the stimulus, thereby giving participants the opportunity to see the moving  
18 object for the duration of the 100ms intermittent “open” interval. That said, it is worth noting  
19 that we were unable to equate the amount of light transmitted through the different eyewear,  
20 and thus reaching the eye, in the “open” state. Although a potential confound, we suggest that  
21 any difference in light transmission between the stroboscopic eyewear in the “open” state and  
22 the control eyewear is unlikely to have influenced the observed results. For instance,  
23 participants in our study reported being able to see normally through both eyewear (i.e.,  
24 stroboscopic eyewear in the “open” state), whereas others have found that throwing and  
25 catching drills are not sufficiently demanding when the stroboscopic eyewear are set to level 1

1 (100ms open, 67ms closed)<sup>5</sup>. Finally, we also measured sustained attention in a computer-based  
2 vigilance task (PVT). This confirmed that the majority of participants became less accurate and  
3 more variable as a function of time-on-task. However, the vigilance decrement in the computer-  
4 based task was not significantly correlated with the change in coincidence-anticipation  
5 performance (i.e., accuracy and variability). This finding was not unexpected given that the  
6 two tasks have different processing and response demands, and consequently might be affected  
7 differently by the vigilance decrement<sup>10,26</sup>.

8         The notion that practicing coincidence-anticipation in stroboscopic vision engages  
9 attention is consistent with the “immediate benefit” reported by Smith & Mitroff<sup>6</sup>. In their study,  
10 participants’ coincidence-anticipation behaviour was significantly more accurate in a normal  
11 vision post-test immediately after practicing for 5-7 minutes in a stroboscopic vision condition  
12 compared to a normal vision condition. We concur with the authors’ suggestion that this effect  
13 was not evidence of long-term improvements due to learning, and instead that brief exposure  
14 to stroboscopic vision could be used to enhance performance when needed in specific game  
15 situations (i.e., before a baseball player prepares to bat). Interestingly, there is also some  
16 evidence that stroboscopic vision can be used to prevent and accelerate rehabilitation from  
17 injury<sup>27</sup>. However, as with studies that have shown improvements in psychomotor and function  
18 following stroboscopic vision training, it remains to be determined to what extent the benefits  
19 are due to an increase in attentional resource in order to cope with increased task difficulty  
20 and/or redirection of attention to alternative sources of information (e.g., somatosensory and  
21 vestibular inputs in the case of ACL injury).

22         Notably, while the current study used eyewear that are no longer available, there are  
23 alternative commercial eyewear (e.g., PLATO Visual Occlusion Spectacles; Senaptec Strobe;  
24 Visionup Strobe Glasses) that permit greater control over the duration of the open and closed  
25 states. While not the aim here, in future work it will be relevant to determine whether resistance

1 to a vigilance decrement in stroboscopic vision is influenced by factors such as the amount of  
2 light transmitted through the lenses of the eyewear and the strobe rate, both of which could  
3 influence the perception of motion and form. For instance, we used a strobe rate of 4Hz in the  
4 current study, but a lower strobe rate requiring longer intervals of extrapolation would  
5 potentially place greater demand on visual-spatial memory, thus more quickly leading to  
6 overload. Alternatively, practicing at a higher strobe rate requiring shorter intervals of  
7 extrapolation could quickly become less demanding, thus leading to disengagement. In this  
8 respect, the use of a “levelling-up” procedure whereby strobe rate is progressively reduced  
9 based on performance success<sup>7</sup> would seem justified. Finally, an interesting question from the  
10 current study is whether alternating between periods of stroboscopic vision and normal vision  
11 during practice might have additional benefit. For instance, practice in stroboscopic vision  
12 might enable participants to offset the monotony of practicing in normal vision alone, thereby  
13 facilitating improved processing of relevant information and better learning.
