ABSTRACT

Very long baseline interferometry radio images recently proved to be essential in breaking the degeneracy in the ejecta model for the neutron star merger GW170817. We discuss the properties of synthetic radio images of merger jet afterglows by using semi-analytical models of laterally spreading or non-spreading jets. The image centroid initially moves away from the explosion point in the sky with apparent superluminal velocity. After reaching a maximum displacement, its motion is reversed. This behaviour is in line with that found in full hydrodynamic simulations. We show that the evolution of the centroid shift and the image size are significantly different when lateral spreading is considered. For Gaussian jet models with plausible model parameters, the morphology of the laterally spreading jet images is much closer to circular. The maximum displacement of the centroid shift and its occurrence time are smaller/earlier by a factor of a few for spreading jets. Our results indicate that it is crucial to include lateral spreading effects when analysing radio images of neutron star merger jets. We also obtain the viewing angle θ_{obs} by using the centroid shift of radio images provided the ratio of the jet core size θ_c and θ_{obs} is determined by afterglow light curves. We show that a simple method based on a point-source approximation provides reasonable angular estimates (10–20 per cent errors at most). By taking a sample of laterally spreading structured Gaussian jets, we obtain $\theta_{\text{obs}} \sim 0.32$ for GW170817, consistent with previous studies.

Key words: – transients: gamma-ray bursts; transients: neutron star mergers; physical data and processes: gravitational waves; methods: numerical.

1 INTRODUCTION

Shortly after the detection of gravitational waves (GWs) from the binary neutron star (NS) merger, GW170817, its electromagnetic (EM) counterpart was discovered in the S0 galaxy NGC 4993 (e.g. Coulter et al. 2017; Soares-Santos et al. 2017). This transient was subject to an unprecedented follow-up campaign across the EM spectrum (e.g. Abbott et al. 2017). The counterpart was found to be made up of several components: a prompt short gamma-ray burst (GRB) detected 1.7 s after the merger, a kilonova, and a broad synchrotron afterglow, first detected 9 d post-merger at X-ray wavelengths; see Margutti & Chornock (2020) for a review of GW170817 and Metzger (2019), Burns (2020), and Nakar (2020) for reviews of EM counterparts to GW detectable compact binary mergers.

In addition to the merger afterglow light curves, very long baseline interferometry (VLBI) radio images were obtained (Mooley et al. 2018; Ghirlanda et al. 2019). Mooley et al. (2018) presented radio images at 75 and 230 d post-merger, finding an image centroid displacement of $\sim 2.67 \pm 0.2$ mas in the sky, and implying a mean apparent velocity $\beta_{\text{app}} = 4.1 \pm 0.5$; Ghirlanda et al. (2019) confirmed this result with a radio image obtained at 207 d post-merger. This, along with the steep post-peak afterglow decline (Lamb, Mandel & Resmi 2018; Troja et al. 2018, 2019; Lamb et al. 2019b), broke

the degeneracy between a wide quasi-isotropic ejecta and a narrow core-dominated jet, confirming the emission was from the latter.

VLBI images are also important for breaking degeneracies in parameter estimation from light curves. Nakar & Piran (2020) showed that afterglow light curves observed around their peak time T_p cannot constrain the observing angle, θ_{obs} , but only determine the ratio of the observing angle θ_{obs} to the jet opening angle, θ_c (or core size for a core-dominated structured jet). This leads to degeneracy among the parameters $\{\theta_{\text{obs}}, \theta_c, l, \epsilon_B\}$, where $l \sim (E/nm_p c^2)^{1/3}$ is the Sedov length, n is the ambient density, m_p is the proton mass, and ϵ_B is the fraction of shock energy in the magnetic fields. This degeneracy can be broken by the observation of afterglow images (the centroid shift around the peak time) or observing the light curve transition to the subrelativistic phase (Nakar & Piran 2020).

GWs from compact binary mergers provide a luminosity distance D_L that is independent of the cosmological distance ladder (Schutz 1986; Holz & Hughes 2005). Therefore, well-localized GW signals can in principle be used to estimate Hubble’s constant H_0 if combined with EM redshift measurements (e.g. Mastroianni et al. 2020). However, the distance D_L and inclination with respect to the binary plane θ_{obs} are entangled in the GW strain (Misner, Thorne & Wheeler 1973; Holz & Hughes 2005). Without accurate GW polarization measurements to obtain θ_{obs} , this degeneracy leads to additional uncertainties in D_L .

Radio images were used in Mooley et al. (2018) and Ghirlanda et al. (2019) to constrain θ_{obs} . These data were subsequently used by Hotokezaka et al. (2019) and Wang & Giannini (2020) to constrain the Hubble constant to $H_0 = 68.9_{-4.6}^{+4.7}$ km s⁻¹ Mpc⁻¹

* E-mail: joseph.fdez21@gmail.com

and $H_0 = 69.5^{+4}_{-4}$ km s⁻¹ Mpc⁻¹, respectively. The semi-analytical afterglow models used in these works were limited to non-spreading jets.

GRB and merger jets have been studied extensively in the literature. Semi-analytical models based on non-spreading jets have been successful in the study of afterglow light curves. However, jets are expected to laterally expand at late times. As lateral spreading is most significant at late times, after the light-curve peaks, this effect is often not included in semi-analytical modelling (e.g. Ghirlanda et al. 2019; Salafia et al. 2019; Beniamini, Granot & Gill 2020). However, lateral spreading hastens the light-curve peak. In the case of afterglows observed off-axis, it also steepens the rise of the light curve (Lamb et al. 2021). As we show in this work, it can also modify the properties of radio images. Therefore, inclusion of spreading effects is crucial to study the light curves and images. In this paper, the properties of synthetic images of both non-spreading and laterally spreading jets are studied. In Section 2, we describe the numerical method used to model the images. In Section 3, we consider laterally spreading/non-spreading jets to evaluate the afterglow images. We demonstrate the importance of including lateral spreading in semi-analytical image calculations. In Section 4, the results are applied to a GW17017-like system. Summary and conclusions are given in Section 5.

2 NUMERICAL MODEL

2.1 Jet dynamics

We consider a spherical shell, with energy E and mass $M = E/\Gamma_0 c^2$ expanding adiabatically with an initial Lorentz factor Γ_0 into a cold and uniform circumburst medium (CBM) of particle density n . By considering conservation of the stress-energy tensor, it can be shown that the Lorentz factor Γ of the shell evolves with swept-up mass m as (Pe'er 2012)

$$\frac{d\Gamma}{dm} = -\frac{\hat{\gamma}(\Gamma^2 - 1) - (\hat{\gamma} - 1)\Gamma\beta^2}{M + m[2\hat{\gamma}\Gamma - (\hat{\gamma} - 1)(\Gamma + \Gamma^{-2})]}, \quad (1)$$

where $\beta = \sqrt{1 - \Gamma^{-2}}$ is the velocity of the shock in units of c and $\hat{\gamma}$ is the adiabatic index of the fluid (see Pe'er 2012 and Lamb et al. 2018 for details). Because of the relativistic beaming effect, the radiation from a jet can be described by a spherical model with an isotropic explosion energy E . The actual energy in the jet with a solid angle Ω is given by $(\Omega/4\pi)E$, and as the bulk of the system is causally disconnected from its edge the spherical model holds while $\Gamma > > 1/\theta_j$, where θ_j is the half-opening angle of the jet. As the jet decelerates, information about pressure gradients, transported by sound waves, can reach the edges, forcing them to spread laterally. To model this spreading effect, we follow Granot & Piran (2012). The opening angle θ_j is constant for $R < R_d$, where $R_d = l/\Gamma_0^2$ is the deceleration radius. The shell has decelerated to $\Gamma \approx \Gamma_0/2$ at this radius. For $R > R_d$, we approximate the lateral spreading of a jet (spreading cases) as¹

$$\frac{d\theta_j}{d \ln R} = \frac{1}{\Gamma^2 \theta_j}. \quad (2)$$

Since initially $\Gamma\theta_j \gg 1$ is satisfied, lateral spreading is negligible. After the jet break, when $\Gamma \sim 1/\theta_j$, the opening angle can grow

¹This corresponds to the $a = 1$ case in Granot & Piran (2012). In their recipe, this approximation is valid in both the relativistic and Newtonian regimes.

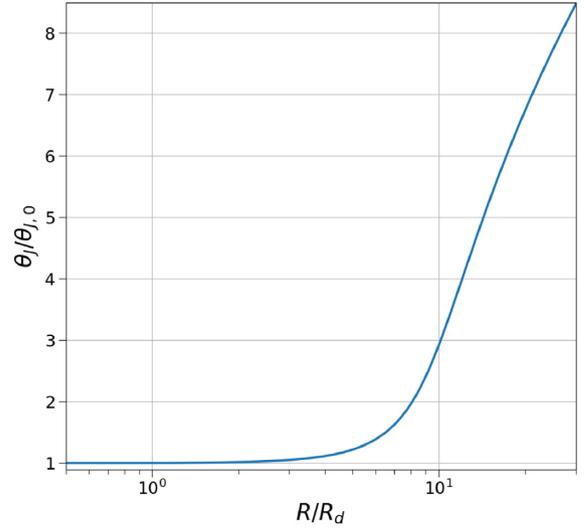

Figure 1. Evolution of the opening angle θ_j in units of its initial value $\theta_{j,0}$.

quickly (e.g. Granot & Piran 2012). The swept-up mass evolves as

$$\frac{dm}{dR} = 2\pi n m_p \left[(1 - \cos \theta_j) R^2 + \frac{1}{3} \sin \theta_j R^3 \frac{d\theta_j}{dR} \right], \quad (3)$$

where it is assumed that the jet front is a conical section of a sphere. For the non-spreading case, equation (3) gives $m = (\Omega/3) n m_p R^3$.

In the thin-shell approximation, photons are emitted from the blast wave surface. The arrival time T (i.e. observer time) of photons emitted from a fluid element at a radius R is given by (e.g. Lamb et al. 2018; Resmi et al. 2018; Lu, Beniamini & McDowell 2020)

$$T(R, \alpha) = \int_0^R \frac{dR}{\beta c} - \frac{R}{c} \cos \alpha, \quad (4)$$

where α is the angle between the emitter's direction of motion and the observer line of sight (LOS).

To illustrate the typical jet evolution, we consider a jet with parameters $E = 5 \times 10^{51}$ erg, $\Gamma_0 = 100$, initial half-opening angle $\theta_{j,0} = 10^\circ$, and $n = 10^{-2}$ cm⁻³; throughout this section, the on-axis case is assumed ($\theta_{\text{obs}} = 0$). The dynamical equations (1), (2), and (3) are solved using a fourth-order Runge–Kutta scheme. The deceleration radius for these parameters is $R_d = 2 \times 10^{17}$ cm, which corresponds to an on-axis deceleration time $T_d \approx 300$ s $\sim 4 \times 10^{-3}$ d. Fig. 1 shows the evolution of the opening angle θ_j in units of its initial value $\theta_{j,0}$ as a function of the radius of the shell. The opening angle initially grows slowly, and by the jet break, when $\Gamma \sim 1/\theta_j$ and when the jet has expanded to a radius $R \approx 5R_d$ (or equivalently at a time $T \approx 1.3$ d for an on-axis observer), the opening angle has grown by a factor of 1.25. As the amount of swept-up mass is larger in the spreading case, the spreading jet decelerates faster. This is illustrated in Fig. 2, which shows the evolution of R (solid curves) and Γ (dashed curves) as a function of T where T is evaluated for $\alpha = 0$. The blue lines correspond to the laterally spreading case, and the red lines correspond to the non-spreading case. The non-spreading jet begins to lead the spreading jet after $T \sim 1$ d, and by $T = 75$ d has a radius that is 50 per cent larger than the spreading jet. The initial evolution of the Lorentz factor Γ in both cases is similar. After the initial coasting phase, Γ decreases as $\Gamma \propto T^{-3/8}$, as is expected for a relativistic blast wave. After $T \sim 0.5$ d, the evolution of the two systems separates. The spreading jet presents a steeper decay until $T \approx 1000$ d, when its Lorentz factor begins to flatten as the system approaches the subrelativistic regime.

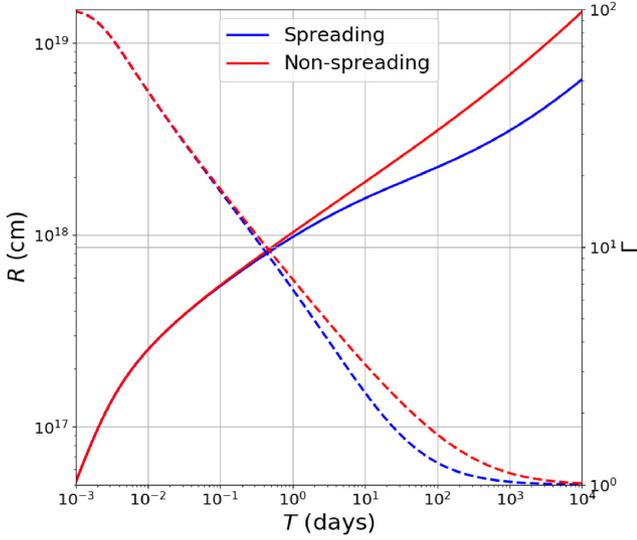

Figure 2. Evolution of a top-hat jet radius R (solid lines, left vertical axis) and Lorentz factor Γ (dashed lines, right vertical axis), as a function of T where T is evaluated for $\alpha = 0$. Blue and red lines indicate the spreading and non-spreading cases, respectively.

2.2 Synchrotron spectrum

The shock accelerates the CBM electrons to a power-law distribution $N(\gamma_e)d\gamma_e \propto \gamma_e^{-p}d\gamma_e$, for $\gamma_e > \gamma_m$. Here, ϵ_e is the fraction of shock energy given to the electrons, $\gamma_m = \epsilon_e(p-2)(p-1)^{-1}(m_p/m_e)(\Gamma-1)$ is the minimum electron Lorentz factor, and m_e is the mass of the electron. The magnetic field strength behind the shock is $B = \{8\pi\epsilon_B n m_p c^2 (4\Gamma+3)(\Gamma-1)\}^{1/2}$.

Relativistic electrons emit synchrotron radiation as they gyrate around the magnetic field lines. The characteristic synchrotron frequency is $\nu_{\text{sync}}(\gamma_e) = (qB\gamma_e^2/2\pi m_e c)\delta$, where q is the electron charge and $\delta = \Gamma^{-1}(1 - \beta\cos\alpha)^{-1}$ is the Doppler factor.

The synchrotron spectrum is described by a broken power law with two break frequencies, $\nu_m = \nu_{\text{sync}}(\gamma_m)$ and $\nu_c = \nu_{\text{sync}}(\gamma_c)$, where $\gamma_c = (6\pi m_e c)/(\sigma_T \Gamma B^2 T(\alpha=0))$ (e.g. Sari, Piran & Narayan 1998). The spectrum is given by

$$\frac{F_\nu}{F_{\nu,\text{max}}} = \begin{cases} (\nu/\nu_m)^{1/3} & \nu_m > \nu, \\ (\nu/\nu_m)^{-(p-1)/2} & \nu_c > \nu > \nu_m, \\ (\nu_c/\nu_m)^{-(p-1)/2}(\nu/\nu_c)^{-p/2} & \nu > \nu_c, \end{cases} \quad (5)$$

where the peak flux $F_{\nu,\text{max}} = \delta^3(N_e\sigma_T m_e c^2 B)(12\pi q D_L^2)^{-1}$. Here, N_e is the number of emitting electrons and D_L is the luminosity distance to the source.

2.3 Discretization of the system

We consider an axisymmetric jet and assume that all jet and shocked ambient material is confined to an infinitely thin region (this is known as the *thin-shell* approximation). The jet is initially the polar region of a sphere with half-opening angle θ_j .

For numerical purposes, the jet is divided into a single central spherical cap and $n-1$ rings centred on the jet axis. The central spherical cap is labelled with $k=0$, and the concentric rings by $k=1, 2, \dots, n-1$. The spherical cap has an opening angle $\theta_{b,1}$, and the k -th ring is bounded by two concentric circles on the sphere with $\theta_{b,k}$ and $\theta_{b,k+1}$ given by

$$\theta_{b,k} = 2 \sin^{-1} \left(\frac{k}{n} \sin \frac{\theta_j}{2} \right). \quad (6)$$

The spherical cap is regarded as a single region, and the k -th ring is divided in the azimuthal direction ϕ into $2k+1$ equal-sized regions with boundaries $\phi_{kl} = 2\pi l/(2k+1)$, where $l=0, 1, \dots, k$. This division yields a total of $\sum_{k=0}^{n-1} (2k+1) = n^2$ regions each subtending a solid angle of $2\pi(1 - \cos\theta_j)/n^2$ (Beckers & Beckers 2012). Having divided the jet, the positions of the regions are defined by the radius R and the angles (θ_k, ϕ_{kl}) , where $\theta_k = (\theta_{b,k} + \theta_{b,k-1})/2$ and $\phi_{kl} = (\phi_k + \phi_{k-1})/2$. The coordinate vector $\mathbf{r}_{kl} = (x_{kl}, y_{kl}, z_{kl})$ of the fluid element kl has components

$$\begin{cases} x_{kl} = R \sin \theta_k \cos \phi_{kl}, \\ y_{kl} = R \sin \theta_k \sin \phi_{kl}, \\ z_{kl} = R \cos \theta_k. \end{cases} \quad (7)$$

Given a set of initial conditions, only the radial component R will evolve for a non-spreading jet, whereas for a laterally spreading jet both R and θ_k will evolve, as we discuss in Section 3.

2.4 Construction of light curves and synthetic images

To obtain light curves, we use the procedure outlined in Lamb & Kobayashi (2017) and Lamb et al. (2018). We take a Cartesian coordinate system in which the jet propagates in the z -direction and the observer is in the yz plane. The LOS forms an angle θ_{obs} with the z -axis. The direction along the LOS is defined by the unit vector $\hat{\mathbf{n}}_{\text{obs}} = \sin\theta_{\text{obs}}\hat{\mathbf{y}} + \cos\theta_{\text{obs}}\hat{\mathbf{z}}$. The angle between the LOS and the direction of motion of the fluid element $\hat{\mathbf{r}}_{kl} = \mathbf{r}_{kl}/R_{kl}$, for a non-spreading jet, is given by $\alpha_{kl} = \cos^{-1}(\hat{\mathbf{r}}_{kl} \cdot \hat{\mathbf{n}}_{\text{obs}})$. The contribution of this cell to the light curve at time T is obtained by inverting equation (4) to obtain the observed radius $R_{kl}(T)$, which determines the emission with the formalism detailed in Section 2.2. For a laterally spreading jet, the fluid element also has a sideways expansion velocity. However, the lateral velocity is much smaller than the radial velocity, so the Doppler factor is evaluated using the direction of radial motion only. The light curve is obtained by adding up the contribution of each individual fluid element, i.e. $F_\nu(T) = \sum_{k,l} F_{\nu,kl}(T)$.

The imaging plane is perpendicular to the LOS of the distant observer. Two mutually perpendicular directions in this plane are given by the basis vectors $\hat{\mathbf{x}} = \sin\theta_{\text{obs}}\hat{\mathbf{z}} - \cos\theta_{\text{obs}}\hat{\mathbf{x}}$, $\hat{\mathbf{y}} = \hat{\mathbf{x}}$, where the tildes indicate vectors in the imaging plane, as seen by an off-axis observer. This basis is chosen so that the principal jet moves in the positive \tilde{x} -direction in the imaging plane. Having defined the unit vectors in the imaging plane, the coordinates of the fluid elements in the image are given by $\tilde{x}_{kl} = \mathbf{r}_{kl} \cdot \hat{\mathbf{x}}$ and $\tilde{y}_{kl} = \mathbf{r}_{kl} \cdot \hat{\mathbf{y}}$. The specific intensity or brightness of a given fluid element is obtained from the spectral flux by considering the solid angle subtended by the emitter in the sky.

2.5 Jet structures

Full hydrodynamic simulations show that when a merger jet needs to drill through surrounding ejecta, the emerging jet has a specific structure in energy and Lorentz factor distributions (De Colle et al. 2012; Xie, Zrake & MacFadyen 2018; Gottlieb, Nakar & Bromberg 2020; Nativi et al. 2021). These structures affect the time evolution and shape of afterglow light curves (e.g. Granot et al. 2002; Zhang & Meszaros 2002; Granot & Kumar 2003; Rossi et al. 2004; Wei & Jin 2003; Salafia et al. 2015; Lamb & Kobayashi 2017; Beniamini et al. 2020; Takahashi & Ioka 2021).

Here, we consider a Gaussian jet model characterized by a core with semi-opening angle θ_c within which most of the energy is

contained. The energy per unit solid angle, $\epsilon(\theta)$, and the initial Lorentz factor, $\Gamma_0(\theta)$, distributions are

$$\begin{cases} \epsilon(\theta) = \epsilon_c e^{-\theta^2/\zeta_1\theta_c^2} \\ \Gamma_0(\theta) = 1 + (\Gamma_c - 1)e^{-\theta^2/\zeta_2\theta_c^2}, \end{cases} \quad (8)$$

where the values $\zeta_1 = 1$ and $\zeta_2 = 2$ are assumed (e.g. Lamb & Kobayashi 2018; Resmi et al. 2018; Lamb et al. 2019b). For these coefficients, the deceleration radius R_d does not depend on θ . The structure is imposed as initial conditions for the dynamics.

2.6 Implementation of lateral spreading for structured jets

From equation (2), it can be seen that the degree of lateral spreading depends on the Lorentz factor of the jet and that spreading becomes significant when $\Gamma \sim 1/\theta_j$. To include this effect in the dynamics of a top-hat jet, equation (2) is simply applied for the edges and the spreading is applied to each fluid element accordingly.

For structured jets, the implementation is slightly more complex. The initial conditions are given as a function of θ by equation (8), and the discretization described earlier divides the jet into rings of constant $\epsilon(\theta_k)$, $\Gamma_0(\theta_k)$. Each of these rings has slightly different dynamical evolution; therefore, we assume each ring to be part of a top hat with initial opening angle $\theta_{b,k+1}$. Neglecting the interaction between rings, the dynamical evolution of each ring, including the spreading effect, is approximated using the top-hat jet model.

Similar approaches have been considered in previous studies, including Lamb et al. (2018) and Ryan et al. (2020). While more flexible and significantly less costly to run, the semi-analytical calculations of laterally spreading jet dynamics have limitations. First, this approximation ignores the gradual pressure gradient and instead assumes a sharp density gradient for each ring. Thus, it overestimates the spreading of each part of the jet. Second, the obtained structure after spreading starts is inconsistent in the sense that different initial rings occupy the same region in space and are decelerated independently by the same collected mass. This approximation has not been fully tested for a structured jet (unlike a top-hat jet, where these problems do not exist). Although a detailed comparison with full hydrodynamic simulation results is needed to quantify errors in this approximation, considering the overestimates of the jet spreading, the real centroid shift of jet images (i.e. the full hydrodynamic simulation results) might take an intermediate value of those obtained through our two approximations.

3 SYNTHETIC RADIO IMAGES OF SPREADING OR NON-SPREADING JETS

Recently, 2D (e.g. Granot, De Colle & Ramirez-Ruiz 2018; Zrake, Xie & MacFadyen 2018) and 3D hydrodynamic models (Nakar et al. 2018) have been used to obtain synthetic images in the context of the NS merger event GW170817. Granot et al. (2018) present radio images for a uniform interstellar medium (ISM) and different wind-like profiles. They find that the image centroid is initially dominated by the principal jet contribution, but when the counter jet becomes visible this component becomes dominant rather quickly. Zrake et al. (2018) compare the evolution from successfully launched, anisotropic jets and choked jets, which give rise to a quasi-spherical explosion. They obtain the evolution of the image centroid and width, and find that, for GW170817-like events, the latter may be used to distinguish between the choked and successful jet scenarios.

Semi-analytical models have been used extensively for light-curve calculation, for both simple top-hat jets and diverse structured jets.

Lateral spreading is generally introduced in semi-analytical models by assuming a simplified model, such as the formalism presented in Granot & Piran (2012). Lamb et al. (2018) and Ryan et al. (2020) take similar approaches, modelling this feature as sound-speed expansion of the jet edges. However, the application of semi-analytical models to imaging in the literature is generally limited to non-spreading jets. Semi-analytical imaging was presented in Gill & Granot (2018) for Gaussian and power-law-structured, non-spreading jets; see also Ghirlanda et al. (2019). In Lu et al. (2020), a semi-analytical effective 1D formalism is presented for which lateral spreading is derived by considering momentum conservation and pressure gradients (in this paper the authors show the evolution of the numerical grid points, but explicit imaging is not provided). Duffell & Laskar (2018) have also given detailed studies of the spreading process.

Once the solid angle of the jet increases significantly, the jet decelerates faster. The effect of lateral spreading is not substantially significant in the rising part of the light curves; however, the light curve, where $v < v_m$, peaks earlier when lateral spreading is included. The decay index after the jet break, or peak for an off-axis observer, depends on the lateral spreading.

In this paper, the synthetic radio images of laterally spreading jets are obtained using the semi-analytical model described in the previous section. The deceleration of the jet caused by mass build-up on the shock shell is governed by equation (1), the swept-up mass is given by equation (3), and the evolution of the opening angle is given by equation (2).

Radio imaging has been proposed as a tool to break the degeneracy between radial and angular structured jets (Gill & Granot 2018) or between isotropic and jet-like ejecta (Mooley et al. 2018). In particular, obtaining the image centroid, defined as the surface brightness-weighted centre of the image

$$\tilde{x}_c = \frac{1}{\int I_\nu d\tilde{x}'d\tilde{y}'} \int \tilde{x}' I_\nu d\tilde{x}'d\tilde{y}', \quad (9)$$

was key for this purpose. For spherical blast waves, the centroid does not move, i.e. $\tilde{x}_c = 0$. This is also the case for jets observed exactly on-axis (when the LOS runs exactly along the jet axis). For jets observed off-axis, at early times \tilde{x}_c moves in the principal jet direction. For relativistic jets, we would observe superluminal motion of the jet on the sky if the viewing angle was small.

To illustrate the spreading effects on light curves and images, consider a Gaussian-structured jet with $E_c = 4\pi\epsilon_c = 5 \times 10^{51}$ ergs, $\Gamma_c = 100$, $n = 10^{-2} \text{ cm}^{-3}$, $\theta_{j,0} = 10^\circ$, and $\theta_c = 3^\circ$, and the microscopic parameters $p = 2.16$, $\epsilon_e = 0.1$, and $\epsilon_B = 0.01$ (e.g. Lamb & Kobayashi 2017; Zrake et al. 2018). We consider a luminosity distance to the observer of $D_L = 41.3$ Mpc. Fig. 3 shows the light curves obtained for $\theta_{\text{obs}} = 0^\circ, 20^\circ, 30^\circ$, and 45° . The on-axis light curves are very similar for the non-spreading (top panel) and spreading (bottom panel) cases. For the off-axis cases, the light curves obtained for the laterally spreading jet show a slightly faster rise, an earlier peak time, and a faster post-peak decay. The earlier brightening is due to more mass being swept-up at smaller radii when compared to the non-spreading case. The steeper decay after peak time is again due to lateral spreading transporting energy away from the core (Lu et al. 2020). The peak times for the non-spreading are $T_p \approx 1.4, 33, 97$, and 284 d, and for the spreading jet $T_p \approx 0.8, 20, 51$, and 122 d (for $\theta_{\text{obs}} = 0^\circ, 20^\circ, 30^\circ$, and 45° , respectively).

Fig. 4 shows synthetic radio images of the afterglows for $\theta_{\text{obs}} = 20^\circ$ from the jet axis, at times $T = 44, 75$, and 230 d after the initial explosion. The surface brightness in each image is normalized to $I_{\nu,\text{max}}$, with the colour map covering the range between $0.01I_{\nu,\text{max}}$ and $I_{\nu,\text{max}}$. The red crosses indicate the position of the centroid in

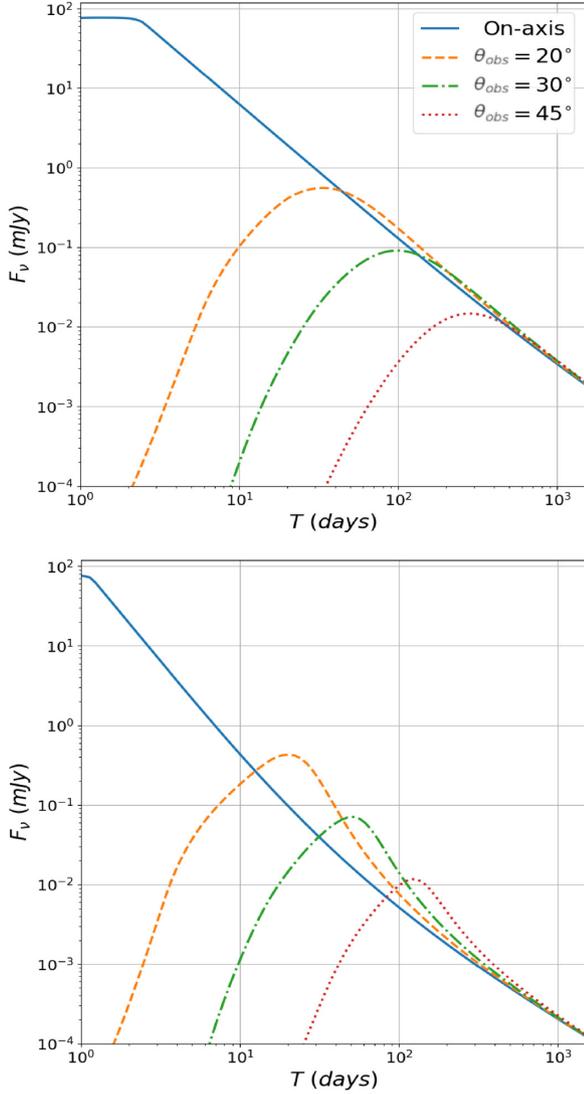

Figure 3. Light curves for a Gaussian jet obtained at frequency $\nu = 5$ GHz for a non-spreading-jet case (top panel) and a case that includes lateral spreading (bottom panel). The light curves correspond to an on-axis observer (solid blue lines) and observers at $\theta_{\text{obs}} = 20^\circ$ (orange dashed lines), $\theta_{\text{obs}} = 30^\circ$ (green dash-dotted lines), and $\theta_{\text{obs}} = 45^\circ$ (red dotted lines).

each image. The counter jet is visible in the images at $T = 230$ d. In the spreading case, the counter jet appears as a brightness excess, as the projections of the principal and counter jets overlap in the imaging plane.

In the non-spreading case (left-hand column), the principal jet always moves in the positive \bar{x} -direction, leaving the explosion origin behind ($\bar{x} = 0$) in the imaging plane. The images resemble a sliced ellipsoid and present a gradual decrease in brightness from front (right-most edge) to back (left-most edge). A ring develops at the back of the image, the edges of which correspond to the wings of the jet. The bright leading section corresponds to the centre of the jet. The extension along the \bar{x} -direction is around two to four times that along \bar{y} . In contrast, the morphology of the laterally spreading jet images is much closer to circular, due to the excess (reduced) growth along \bar{y} (\bar{x}). As before, the images present a dim ring which encloses a brighter region corresponding again to central, more energetic fluid elements. A similar morphology is found at higher inclinations $\theta_{\text{obs}} = 30^\circ$ and 45° . In addition, lateral spreading also causes the fluid

elements to rotate around the origin of the imaging plane. When the jet-opening angle grows to the observing angle, $\theta_j = \theta_{\text{obs}}$, the apparent motion of its outermost components is in the negative \bar{x} -direction. This gives rise to the features described in the following sections, such as the centroid motion reversal.

3.1 Evolution of the centroid of jet images

The spreading and non-spreading cases result in significantly different evolutions for the centroid shifts. In Fig. 5, the evolution of the image centroid is shown for observing angles $\theta_{\text{obs}} = 20^\circ, 30^\circ$, and 45° . The centroid quickly moves away from the explosion point in the sky. At very late times ($T \sim 1000$ d in all three cases for the non-spreading jet), the centroid reverses its motion. For the laterally spreading jet, the early evolution is similar, but the maximum centroid displacement is smaller and is reached much earlier, at $T \sim 340, 335$, and 330 d for $\theta_{\text{obs}} = 20^\circ, 30^\circ$, and 45° , respectively. By these times, the light-curve flux has decreased by a factor of $\sim 180, 45$, and 7 for the spreading jet compared to the peak flux. The centroid position continues to move backwards and crosses $\bar{x} = 0$. It then reverses once more and asymptotically approaches $\bar{x} = 0$ after several thousand days. Similar centroid behaviour was found using 2D hydrodynamic simulations in Granot et al. (2018) (see their figure 6).

To explain this behaviour, the contributions to \bar{x}_c from the principal and counter jet to the centroid are separated for $\theta_{\text{obs}} = 20^\circ$ in Fig. 6 (orange and green dashed lines, respectively). The solid blue line shows the overall centroid evolution for comparison. Initially, the contribution of the principal jet dominates in both jet models. In the non-spreading case (left-hand panels), when the principal jet decelerates sufficiently the counter-jet contribution becomes relevant and the centroid motion reverses. While at early times the jet core dominates the centroid calculation, as it decelerates and becomes less bright the contribution of the slower jet wings becomes more significant. At very late times $T \sim 1200$ d, the principal-jet centroid also reverses its motion as the jet decelerates.

Two factors contribute to the earlier onset of centroid motion reversal in the laterally spreading case. As in the non-spreading case, the motion of the counter jet contributes to the reversal and this happens at much earlier times because the luminosity of the principal jet decays faster. In addition, the edges of the jet expand to $\theta_j > \theta_{\text{obs}}$ and part of the jet begins to move backwards in the imaging plane. Consequently, the expansion becomes more isotropic, which slows down the principal-jet centroid displacement and eventually also contributes to the reversal.

In Fig. 7, the apparent velocity of the centroid in units of c , β_{app} , is shown as a function of T . For all cases, the centroid displacement is initially superluminal, $\beta_{\text{app},c} > 1$. The apparent velocity presents a much steeper decrease in the laterally spreading cases. The threshold $\beta_{\text{app}} < 0$ corresponds to the reversal of the centroid motion, which in all cases peaks at subluminal velocities. After becoming negative, the velocity asymptotically approaches $\beta_{\text{app}} \rightarrow 0$ as both the principal and the counter jet decelerate (this is not shown in the figure for the non-spreading case).

Since light curves peak when the core becomes visible to the observer $\Gamma(\theta_{\text{obs}} - \theta_c) \sim 1$, the apparent velocity of the centroid at the peak time of the light curve can be used to estimate $\Delta\theta = \theta_{\text{obs}} - \theta_c$ (e.g. Mooley et al. 2018; Nakar & Piran 2020). A point source moving with a Lorentz factor Γ at an angle $\Delta\theta$ with respect to the LOS has the maximum apparent velocity $\beta_{\text{app}} = \beta\Gamma = \sqrt{\Gamma^2 - 1}$ for an angle $\sin \Delta\theta = \Gamma^{-1}$. If the apparent velocity is obtained around the peak time, the angle $\Delta\theta$ can be estimated as $\sin \Delta\theta = (1 + \beta_{\text{app}}^2)^{-1/2}$.

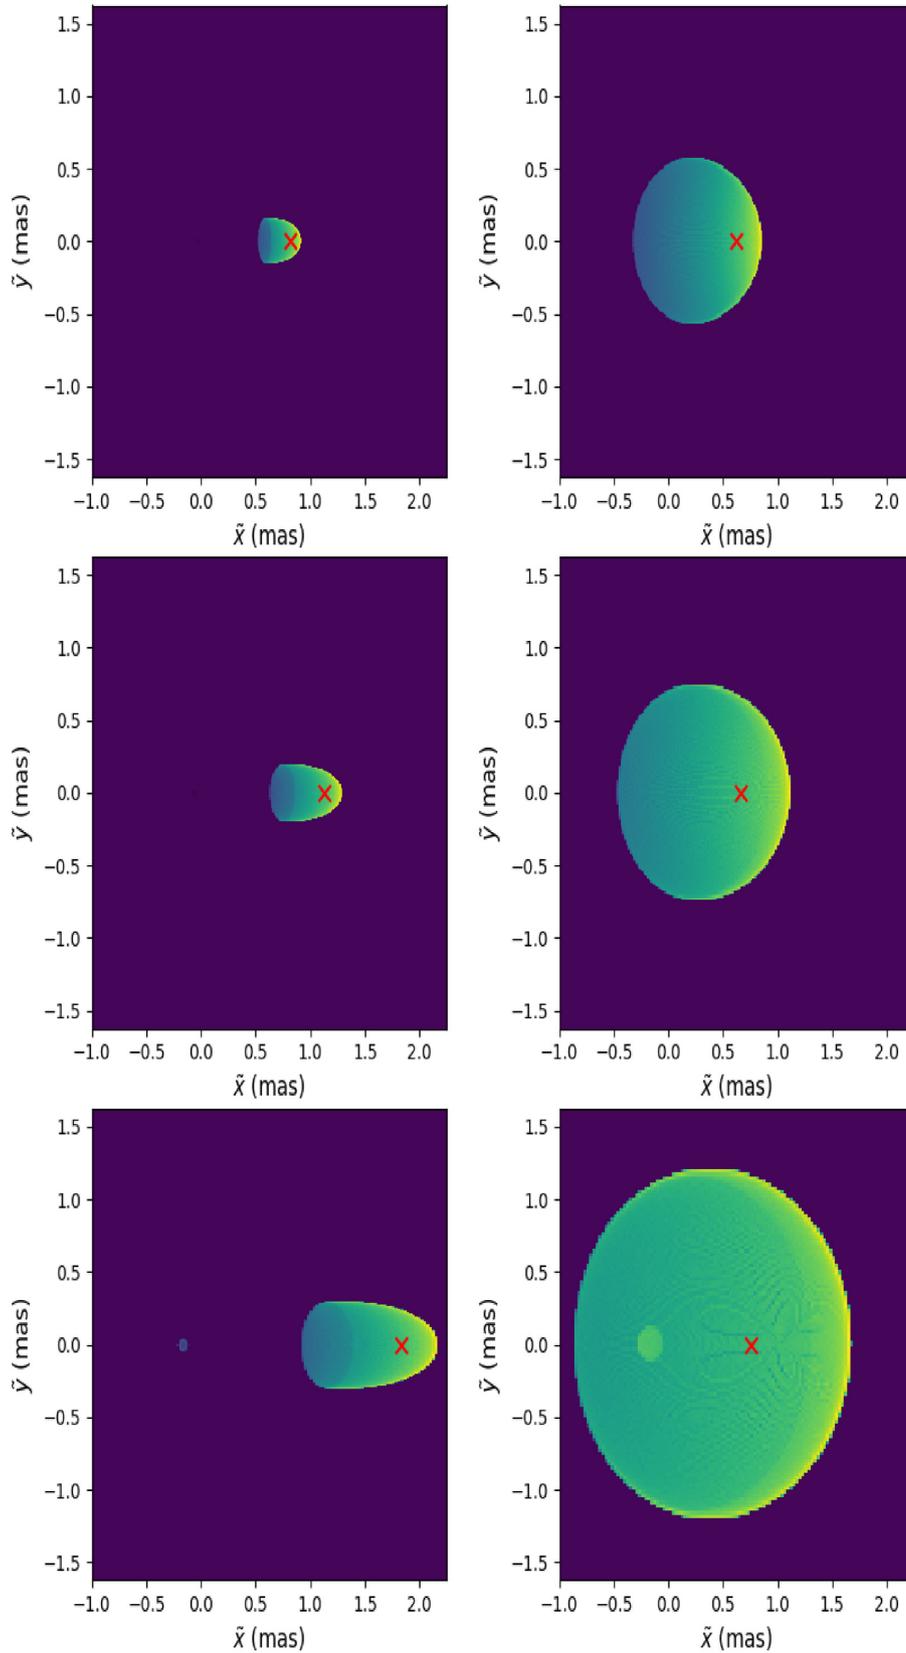

Figure 4. Radio images ($\nu = 5$ GHz) at times 44, 75, and 230 d (top, middle, and bottom panels, respectively) after explosion for an observer with LOS at $\theta_{\text{obs}} = 20^\circ$ from the jet axis and a distance of $D = 41.3$ Mpc from the source. The images are normalized to the maximum brightness $I_{\nu, \text{max}}$ in each frame, with a background threshold set at $0.01I_{\nu, \text{max}}$. The red crosses mark the position of the image centroid. The non-spreading case is shown in the left-hand column and the spreading case in the right-hand column.

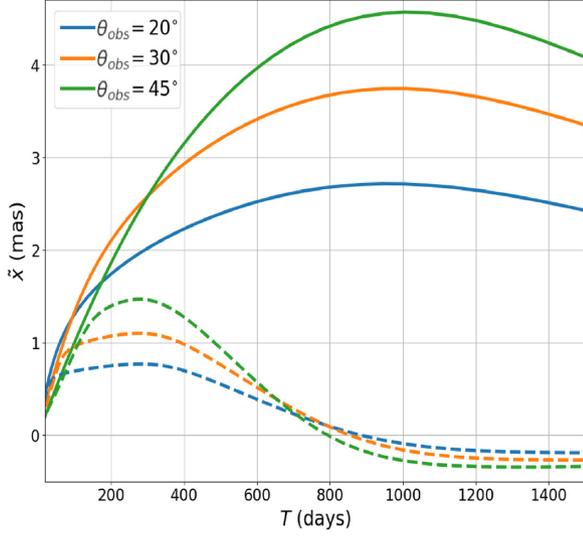

Figure 5. Evolution of the image centroid position \tilde{x}_c as a function of observer time T and observing angle θ_{obs} (blue: $\theta_{\text{obs}} = 20^\circ$; orange: $\theta_{\text{obs}} = 30^\circ$; green: $\theta_{\text{obs}} = 45^\circ$). The solid (dashed) lines are for the non-spreading (spreading) case.

At the peak time of the light curve T_p , the simple estimate of the apparent velocity $\beta_{\text{app}} = \sin^{-2} \Delta\theta - 1 \approx 3.3, 2.0,$ and 1.1 for $\theta_{\text{obs}} = 20^\circ, 30^\circ,$ and 45° , respectively, where we have used the values of $\Delta\theta$ set by the simulations. The values of the β_{app} obtained from the centroid shift and the inferred $\Delta\theta$ are shown in Table 1. The values of the numerical β_{app} are larger than those expected from the simple estimate, implying that $\Delta\theta$ is slightly underestimated in this method. The errors are larger in the spreading case.

3.2 Image structure

The centroid is a robust characteristic of jet images which can be relatively easily obtained from observations. For brighter jets, it might be possible to carry out more detailed analysis to obtain other properties (Zrake et al. 2018). Fig. 8 shows the full width at half maximum (FWHM) along the \tilde{y} -direction, as measured at $\tilde{x} = \tilde{x}_c$. The case of the non-spreading jet presents only modest growth even at late times as the expansion of the jet is preferably along \tilde{x} . As lateral spreading leads to significantly enhanced growth in \tilde{y} , the FWHM grows much faster, roughly as the physical size of the image in the sky. The centroid shift and the evolution of the FWHM can confirm or give a constraint on the lateral expansion law of jets.

Fig. 9 shows the surface brightness distributions along the jet axis

$$I_{v,\text{mean}}(\tilde{x}) = \frac{\int I_v(\tilde{x}, \tilde{y}) d\tilde{y}}{\Delta\tilde{y}} \quad (10)$$

at times $T = 44, 75,$ and 230 d after the explosion, for $\theta_{\text{obs}} = 20^\circ$. A brightness threshold $I_v/I_{v,\text{max}} \geq 0.01$ was set in the images.

The distributions in Fig. 8 trace the morphology of the full images in Fig. 4. For the non-spreading case (top panel), the distributions move to the right (larger \tilde{x}_c) and they become slightly wider as time passes. For the spreading case (bottom panel), the spreading of the distribution is more significant compared to the propagation. The rear edge moves backward as time passes. The peak of the distribution is located slightly behind the front edge, before a sharp dip due to the ring that encloses the central jet material. We find similar results for larger inclinations $\theta_{\text{obs}} = 30^\circ$ and 45° . These results indicate that the

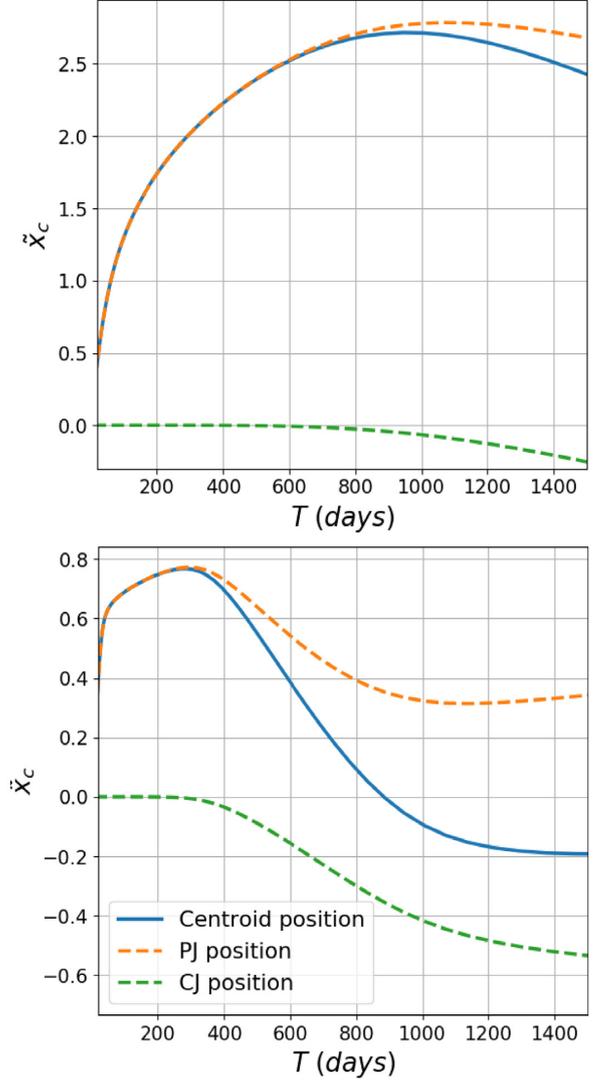

Figure 6. Position of the image centroid \tilde{x}_c (solid blue curve) as a function of time T for the non-spreading (top panel) and spreading case (bottom panel) for $\theta_{\text{obs}} = 20^\circ$. The brightness-weighted contribution of the principal jet (dashed orange curves) and counter jet (dashed green curves) are also shown.

lateral spreading introduces distinguishable features in the brightness distributions from the non-spreading case. In particular, if the reverse motion of the rear edge is observed this would be a signature of the lateral expansion. For bright events, the centroid shift and FWHM evolution measurements might confirm or give a tight constraint on the lateral expansion law of merger jets.

4 APPLICATIONS OF THE SPREADING-JET SEMI-ANALYTICAL MODEL TO GW170817

Afterglow light curves have served as powerful tools to understand the jet physics. However, Nakar & Piran (2020) have discussed in detail (see also Mooley et al. 2018; Ryan et al. 2020) that there is degeneracy among the system parameters. A given light curve can be compatible with a wide range of models, with varying model parameters. Light curves, especially the widths of the light-curve peaks, can constrain only the angular ratio $\theta_{\text{obs}}/\theta_c$, and each angle is not determined separately.

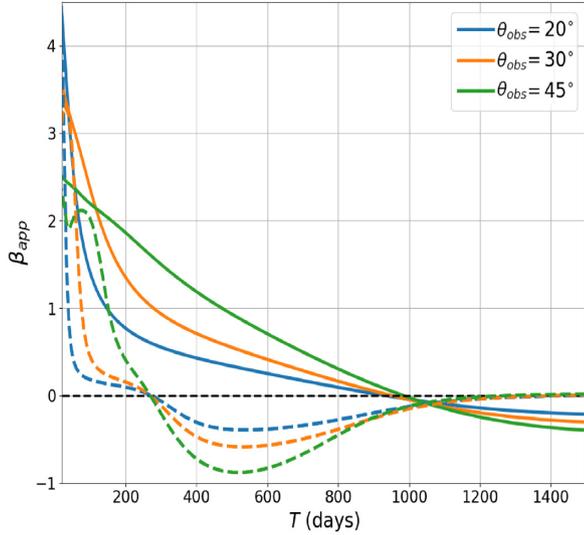

Figure 7. Apparent velocity of the centroid in units of c . Solid (dashed) lines correspond to the non-spreading (spreading) case.

Table 1. Observing angles inferred from the apparent velocity of the radio image centroid at light-curve peak time.

θ_{obs}	β_{app} (coll./spread.)	Inferred $\Delta\theta$ (coll./spread.)	% error
20°	3.5/4.2	$16^\circ/14^\circ$	6% / 19%
30°	2.4/2.7	$22^\circ/21^\circ$	15% / 22%
45°	1.5/1.6	$33^\circ/32^\circ$	21% / 24%

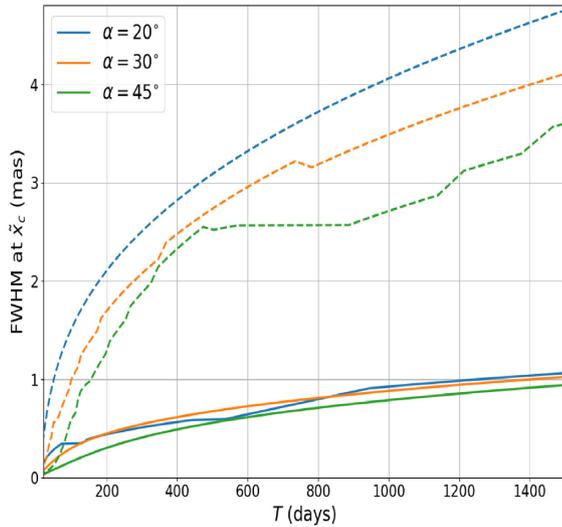

Figure 8. Vertical extent of the radio images, defined as the full width half maximum (FWHM) in the \bar{y} -direction at $\bar{x} = \bar{x}_c$. The solid lines are for a non-spreading jet, the dashed lines for a laterally spreading jet.

To illustrate the degeneracy, five different Gaussian jets are considered, with parameters given in Table 2. These models were obtained by fixing the ratio $\theta_{\text{obs}}/\theta_c$, and scaling θ_{obs} , θ_c , n , and ϵ_B to keep T_p and $F_\nu(T_p)$ constant. We fixed the energy E while varying the CBM density n . The models span two orders of magnitude of n (or equivalently a factor of $10^{2/3}$ in l) and one order of magnitude for ϵ_B . The models were chosen to roughly match radio ($\nu = 3$ GHz) data for the afterglow of the neutron star merger GW170817. The light

Model 2	4.8×10^{-5}	0.02	0.06	0.19	0.28
Model 3	1.7×10^{-4}	0.008	0.07	0.23	0.33
Model 4	4.8×10^{-4}	0.004	0.08	0.26	0.37
Model 5	1.2×10^{-3}	0.003	0.09	0.30	0.42

curves are shown in Fig. 10, in which the light curves are identical around the peak.

The properties of radio images depend directly on the geometry and dynamics of the shock. By combining the constraints from the light curves and images, we can distinguish different models (e.g. Mooley et al. 2018; Ghirlanda et al. 2019; Ryan et al. 2020). Fig. 11 shows radio images obtained for models 1–5 at 75 and 230 d (the days for which VLBI images for GW170818 were reported in Mooley et al. 2018), and around the peak time at 150 d. For these cases, the

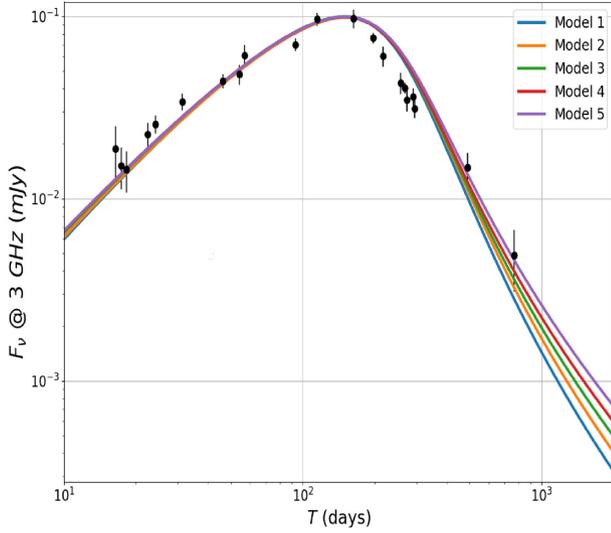

Figure 10. Synthetic light curves for GRB 170817A-like systems obtained using the parameters in Table 2. Data points for 3 GHz VLA observations (from Makhathini et al. 2020) are shown as black circles. The spreading jet model has been assumed.

Table 3. Observable parameters extracted from the synthetic radio images shown in 12.

	Δx_c (mas)	β_{app}	$\Delta\theta$ (rad)	% error (%)
Model 1	3.7	5.6	0.18	3.5
Model 2	3.1	4.7	0.21	4.6
Model 3	2.6	4.0	0.24	4.5
Model 4	2.3	3.5	0.28	5.0
Model 5	2.0	3.1	0.31	5.3

model images also present a brightness distribution that decreases gradually from front to back. Note that the morphology is the same for all models, up to scaling of the image size. This is due to the ratios $\theta_{\text{obs}}/\theta_j = 1.4$ and $\theta_{\text{obs}}/\theta_c = 4.6$ having been fixed (the angle ratios have been determined by the peak of the light curve). The position of the centroid in each image (red crosses) and the displacement with respect to the position at 75 d (solid red lines) is also shown. At 75 d, the centroid calculation is dominated by the leading bright point in the image and as lateral spreading slows the radial expansion of the wings of the shell, the centroid falls behind the the front of the image, as seen in the images for 150 and 230 d post-merger. The values of the centroid displacement between $T = 75$ d and $T = 230$ d, and the apparent velocity computed as $\beta_{\text{app}} = \Delta x_c/c\Delta T$, are reported in Table 3. $\Delta\theta$ is also computed from β_{app} using the point particle approximation as $\sin \Delta\theta = (1 + \beta_{\text{app}}^2)^{-1/2}$. In this case, the approximation results provide a much better estimate of the the inclination, with deviations of the order of a few percent for rather small $\theta_{\text{obs}}/\theta_c$. The errors in the $\Delta\theta$ estimates were larger for the parameter sets discussed in Section 3.1 (i.e. Table 3, 19 – 24 per cent for the laterally spreading jets), in which $\Delta\theta$ was obtained using the point-emitter approximation. We now consider model 3 in Fig. 2, and by changing the viewing angle θ_{obs} (the other parameters including θ_c are fixed), we re-evaluate errors as a function of $\theta_{\text{obs}}/\theta_c$. The results are shown in Fig. 12, where the apparent velocity $\Delta\tilde{x}_c/\Delta T$ have been estimated for two time windows $\Delta T = T_2 - T_1 = 0.5T_p$ or T_p . We find that the errors (or the discrepancy) are larger for larger angle

ratios. However, merger afterglow observations (i.e. detailed light curves and radio images) will be available only for bright events. The detailed afterglow modelling is likely to be carried out only for low-inclination events, for which the point-emitter estimates are accurate, and the apparent velocity estimates are not sensitive to the choice of the time window.

The observed centroid displacement obtained from VLBI imaging between 75 and 230 d post-merger, as reported in Mooley et al. (2018), is shown for comparison (green solid lines delimited by crosses). They found a centroid displacement of 2.7 ± 0.3 mas, equivalent to an apparent velocity $\beta_{\text{app}} = 4.1 \pm 0.5$. Fig. 12 shows how radio imaging can be used for parameter inference. While the details of the morphology of the images are the same for all models, the evolution of the centroid is determined by the growth of the emitting region, which in turn is related to how fast the shock can expand. For example, model 1 (5) involves a slowly (rapidly) expanding jet as the density is the lowest (highest) in the set. Visual inspection shows that model 1 (5) results in excess (too little) centroid displacement to be compatible with observations. Models 2, 3, and 4 provide a centroid displacement in agreement, within error, with the observational value. Note that while this analysis can provides a constraint on the viewing angle, the uncertainty is dominated by the model uncertainties (the prescribed jet structure in the semi-analytical model) and the data (the distance to GW170817 and VLBI uncertainties).

A direct comparison between the observed and numerical centroid shift can provide a constraint on θ_{obs} without using the approximation $\Delta\theta \sim \beta_{\text{app}}^{-1}$ [a similar analysis has been presented in Mooley et al. (2018) using results from hydrodynamic simulations].

The two methods described previously make it possible to break the degeneracy in the light-curve models using two radio images (e.g. Mooley et al. 2018). Fig. 13 shows the centroid evolution for each of the five models where the $\tilde{x}_c - T$ curves do not overlap as long as the centroid does not move backwards. In all cases, the curves behave as broken power laws $\tilde{x}_c \propto T^\omega$, where it is found that $\omega \approx 0.86$ provides a good fit until the light-curve peak time $T \sim 150$ d (dashed lines in the figure), and the curve is flattened as $\omega \approx 0.4$ since after the peak the emission is dominated by the core radiation; assuming the simple spreading jet $\Gamma \sim T^{-1/2}$, the centroid shift can be approximated as $\tilde{x}_c \sim \beta_{\text{app}} T \sim T^{1/2}$. Since the jet wings propagate slowly, the small contribution might make the scaling index smaller in the numerical model.

5 CONCLUSIONS

We have presented radio image calculations from semi-analytical modelling, focusing on comparison between spreading and non-spreading approximations. We have also shown a comparison of these models to the analytical point-source approximation and a comparison of the spreading-jet semi-analytical model to the observations of GW170817.

While spreading is not immediately apparent in the rising phase of afterglow light curves, it affects the slope and peak time, and can certainly affect images. We find that lateral spreading has an important effect on the morphology of the images and the evolution of the centroid even at early times. It is crucial to include proper lateral spreading effects when analysing radio images of neutron star merger jets at late times.

If neutron star mergers happen in a higher density or/and higher pressure region compared to that where usual short GRBs have been detected (e.g. the discs of active galactic nuclei; Perna et al. 2021), the lateral expansion law of a jet might deviate from a simple jet hydrodynamic model. Jet radio images might be able to reveal such

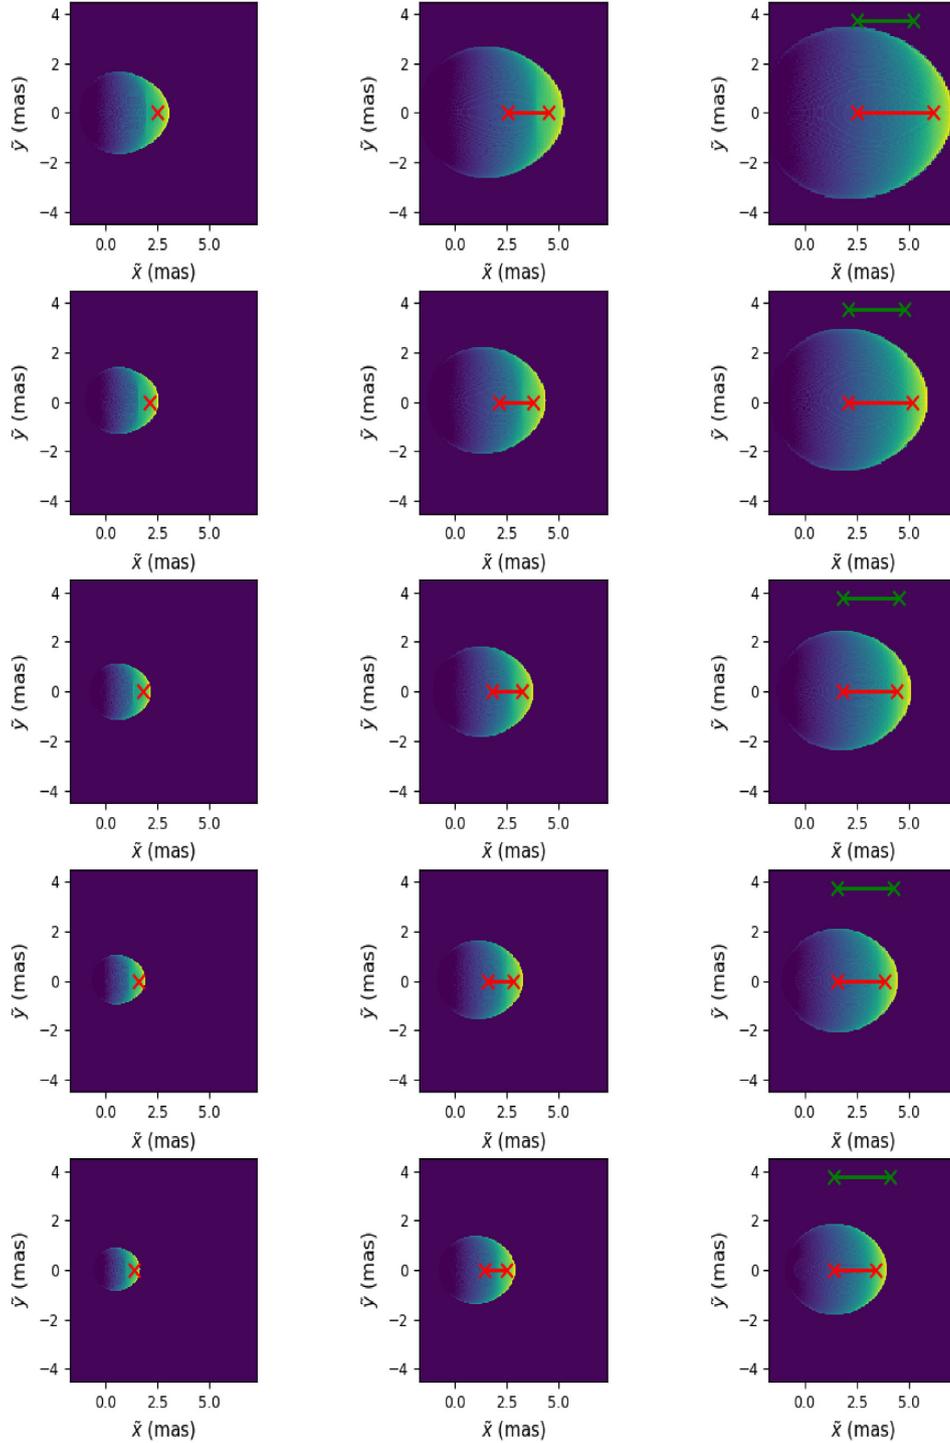

Figure 11. Synthetic radio images ($\nu = 4.5$ GHz) corresponding to the degenerate light curves in Fig. 10. The rows correspond to models 1–5, respectively. The left-hand, central, and right-hand columns correspond to times $T = 75, 150,$ and 230 d. The centroid positions are shown with red crosses, and the centroid displacement with respect to $T = 75$ d is shown with red lines. The centroid displacement reported in Mooley et al. (2018) is shown with green lines. The surface brightness in each image is normalized to $I_{\nu, \text{max}}$, with the colour map covering the range $0.01 I_{\nu, \text{max}}$ to $I_{\nu, \text{max}}$.

confinement effects, although observations of such events are likely to be very challenging due to the distance to the sources and/or the background noises.

We study two methods to determine the viewing angle from radio images: the point-emitter approach $\Delta\theta \sim \beta_{\text{app}}^{-1}$ (e.g. Rees 1966; Mooley et al. 2018) and direct comparison of two or more images (e.g. Mooley et al. 2018) by using a sample of Gaussian

structured jets with parameters that can roughly explain the light curve of the GW170817 afterglow. The direct comparison of the centroid displacements gives the viewing angle $\theta_{\text{obs}} \approx 0.32$, which is consistent with previous studies (e.g. Mooley et al. 2018; Ghirlanda et al. 2019; Hotokezaka et al. 2019; Lamb et al. 2019a; Troja et al. 2019). We find the simpler point-emitter approximation is accurate especially for the GW170817 case.

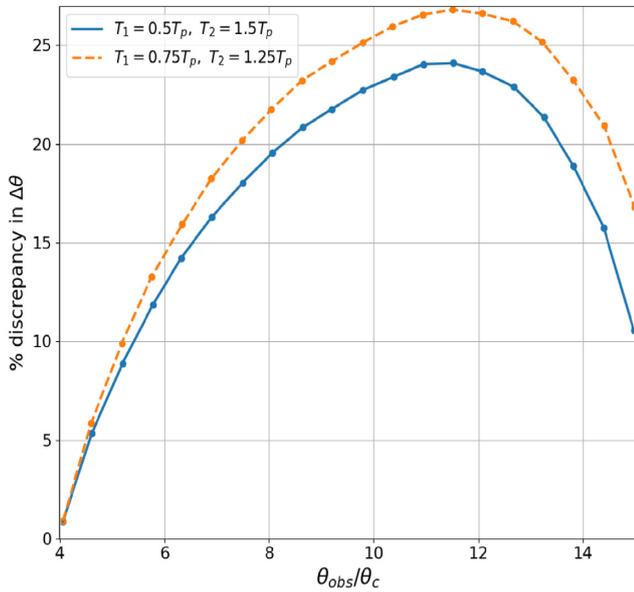

Figure 12. Error in the estimation of θ_{obs} from synthetic images as a function of $\theta_{\text{obs}}/\theta_c$ for two different observing windows. Averaged brightness distributions for $T = 44, 75,$ and 230 d (blue, orange, and green). Top panel: non-spreading case. Bottom panel: laterally spreading case. The distributions were obtained for $\theta_{\text{obs}} = 20^\circ$.
