Abstract

Background: Zebrafish (*Danio rerio*) are increasingly being used to model anxiety. A common behavioral assay employed for assessing anxiety-like behaviors in zebrafish is the "novel tank test". We hypothesized that using deeper tanks in this test would result in greater between-individual variation in behavioral responses and a more 'repeatable' assay.

New methods: After mapping the literature and identifying common behavioral parameters used in analysis, we performed novel tank anxiety tests in both custom-designed 'tall' tanks with increased depth and 'short' trapezoidal tanks. We compared the repeatability of the behavioral parameters between tall and short tanks and also investigated sex differences.

Results: Overall, regardless of tank depth, almost all behavioral parameters associated with anxiety in zebrafish were significantly repeatable ($R = 0.24$ to 0.60). Importantly, our tall tanks better captured between-individual differences, resulting in higher repeatability estimates (average repeatability tall tanks: $R = 0.46$; average repeatability short tanks: $R = 0.36$) and clearer sex differences.

Conclusions: Our assay using tall tanks has advantages over tests based on short tanks which underestimate repeatability. We argue that use of deeper tanks will improve the reliability of behavioral data across studies using novel tank tests for zebrafish. Our results also call for increased attention in designing the most appropriate assay in biomedical and behavioral sciences as current methods may lack the sensitivity to detect subtle, yet important, information, such as between-individual variation, an important component in assessing the reliability of behavioral data.

Keywords: Zebrafish, Anxiety, Repeatability, Sex, Depth, Dimension

1. Introduction

It is important to infer an animal's internal state to gain insight into why they make certain decisions (Kennedy et al., 2014). Inference into their internal state also provides information regarding the animal's welfare, care requirements, preferences, and dislikes (Mason & Mench, 1997). However, given our inability to directly communicate with animals, inferring internal state is challenging (Corrales-Carvajal et al., 2016), and studying behaviour remains the best option. A range of behavioral assays have been developed and are widely used as important indicators of internal state, such as anxiety (Brown & Bolivar, 2018). Anxiety is defined as "a psychological, physiological, and behavioral state induced in animals and humans by a threat to well-being or survival, either actual or potential" (Steimer, 2002). In humans, anxiety is characterized by excessive worry, hyperarousal, and debilitating fear, and is prevalent worldwide in many population subgroups (Remes et al., 2016). Anxiety is also associated with a range of other health issues (Culpepper, 2009) and places heavy economic burden on affected individuals (Konnopka & König, 2020). Consequently, the importance of anxiety research using animal models has significantly increased over the last several decades (Harro, 2018).

Animal models are powerful for answering anxiety related questions, and are often grouped into two subclasses (Clement & Chapouthier, 1998). The first subclass involves paradigms which assess an animal's conditioned response to aversive stimuli (Freudenberg et al., 2018). The second subclass includes ethological paradigms, which involve the animal's natural reactions to a novel environment (unconditioned response) (Bourin, 2015). The latter attempts to emulate natural conditions under which anxious states are elicited (Bourin, 2015). Classic ethological tests include the open field test (Kraeuter et al., 2019) and elevated plus maze (Pellow et al., 1985). While rodents (rats and mice) are the most commonly used animals in these tests, other animal models have become popular in recent times (Steimer, 2011).

Zebrafish (*Danio rerio*) are increasingly being used as an animal model for addressing anxiety related questions (Blaser & Rosemberg, 2012). They are inexpensive to maintain, reproduce readily and are easy to experimentally manipulate. These features make zebrafish ideally suited for behavioural work provided high-throughput screening methods are available (Nguyen et al., 2013). In addition, they display homologies to humans in key genetic, physiological and behavioral features of stress regulation (Griffiths et al., 2012; Howe et al., 2013; Stewart et al., 2014). Most relevantly, they possess a complex behavioral repertoire (Kalueff et al., 2013) and can be phenotyped to measure their state of anxiety (Stewart et al., 2012). A standard method used to measure zebrafish anxiety is the "novel tank diving test" (ethological paradigm). This method exploits the zebrafish's natural tendency to dive, freeze and reduce exploration in unfamiliar environments (Egan et al., 2009). Typically, the novel environments (tanks) used in zebrafish experiments have limited depth.

81 However, there seems little to no research on using tanks that have increased depth , despite the
82 fact that zebrafish are known to prefer greater surface depth (Blaser & Goldsteinholm, 2012). We
83 hypothesize that tanks with increased depth will result in more variation in behavioral responses
84 among individuals, and thus provide a more 'repeatable' assay. Repeatability (R), also known as
85 intra-class correlation (ICC), is the proportion of phenotypic variation attributed to between-
86 subject (or between-individual) variation (Nakagawa & Schielzeth, 2010). Repeatability is an
87 important index used to quantify the measurement accuracy or constancy of phenotypes.
88 Research has shown that a wide range of behavioral traits are more consistent than previously
89 thought (Bell et al., 2009). This warrants the inclusion of repeatability as an essential index in
90 assessing the accuracy of behavioral studies (Rudeck et al., 2020). Zebrafish display between-
91 individual variation in anxiety; that is, anxiety is a repeatable trait (Thomson et al., 2020).
92 However, an anxiety assay with low sensitivity could fail to adequately quantify between-
93 individual variation. We hypothesized that increasing tank depth in novel tank diving tests would
94 increase between-individual variation, allowing us to develop a more effective assay.
95
96 An effective assay can accurately capture differences both between groups and individuals.
97 Behavior is a labile trait (West-Eberhard, 2003) and although it is generally repeatable, on
98 average this repeatability is low, with much of the behavioral variation occurring within
99 individuals, rather than between individuals (Bell et al., 2009). As such, an assay with low
100 repeatability (or high within-individual variation) masks differences between individuals and
101 consequently between groups (that is, variation between two sets of individuals). For example,
102 time spent in the low zone is one of several behavioral parameters used to assess an anxious state
103 in zebrafish in novel tank tests (Maximino et al., 2010). A less effective assay will represent
104 overall behavior as uniform due to the lack of variation between individuals (i.e., all zebrafish
105 are spending similar times at the bottom of the tank). In contrast, an effective assay will capture
106 variable times between individuals and consequently, between groups. Such an assay increases
107 the ability of researchers to make accurate conclusions, for instance regarding treatment efficacy
108 (Senior et al., 2016). Therefore, assays with higher repeatability are usually better able to
109 distinguish differences between groups through greater capturing of between-individual variation
110 or avoiding within-individual variation which overrides behavioral differences among
111 individuals (cf. Fisher et al., 2018; Rudeck et al., 2020).
112
113 Here, we describe development of an efficient, new and repeatable anxiety assay for zebrafish.
114 Our main aims for this study are threefold. First, we mapped the literature regarding novel tank
115 anxiety tests in zebrafish. By doing so, we obtained an overview of the main behavioral
116 parameters used to assess anxiety, as well as other information, such as types and dimensions of
117 tanks used. Second, we performed novel tank anxiety tests in both custom-designed 'tall' tanks
118 with increased depth and 'short' trapezoidal tanks. Thus, we examined differences in behavioral
119 parameter measurements (as identified in our survey) between these two types of tanks. Third,
120 we compared the repeatability of the behavioral parameters between tall and short tanks. In

121   addition, we investigated sex differences, as they are ubiquitous and there has been repeated calls

122   for inclusion of sex as an important biological variable in experiments (Jenkins, 2011;

123   Nakagawa et al., 2007).

2. Materials and methods

2.1 Anxiety survey

We performed a systematic review/survey of the academic literature using the online database *Scopus* in May 2020. We used the following search string:

TITLE-ABS-KEY ("zebrafish" OR "danio rerio" OR "zebra fish" OR "D*rerio") AND ("anxiety-like behaviour*" OR "anxiety-related behaviour*" OR "anxiety test" OR "anxiety assay" OR "tank test" OR "novel tank test" OR "diving test" OR "novel tank" OR "novel tank diving test" OR "video tracking" OR "novel environment" OR "novel tank dive test") AND NOT (bovine OR sheep OR pig* OR drosophila OR cattle OR bull OR vitro OR cow) AND NOT TITLE (women OR men OR patient* OR human* OR child*) AND (LIMIT-TO (DOCTYPE , "ar"))

Our search in Scopus yielded 336 results. We screened titles and abstracts of downloaded bibliometric records using Rayyan QCRI (Ouzzani et al., 2016). We randomly selected the first 50 experimental studies (Table S8) that met our inclusion criteria. To be included, studies had to be empirical work using laboratory zebrafish in a novel tank test to measure anxiety-like behavior. We then coded experiment-level information from the included studies, such as study focus (e.g. behavioral, medical), treatment (e.g. drugs), and tank type (e.g. rectangular, trapezoidal). We extracted numbers pertaining to tank capacity, tank dimensions, duration of assay and sample sizes, and coded zebrafish behavioral parameters used to assess an anxiety state (available with R code as supplemental files; see section 2.6 below for link). Following extraction, we tallied behavioral parameters and selected seven behaviour measurements (for details, see Results).

2.2 Zebrafish husbandry

Mixed Wildtype (WT) zebrafish stock were raised and maintained in a Tecniplast Zebtec System at 28°C under a 12-h light:12-h dark cycle at the Garvan Institute of Medical Research, Sydney, Australia. Adult zebrafish were housed in 3.5L tanks (max 24 fish per tank in accordance with established Garvan Biological Testing Facility Guidelines GLZ02), and larval zebrafish until 1 month of age were housed in 1.1L tanks (max 40 fish per tank). These housing procedures were also established to reduce impact of dense conditions on growth (Hazlerigg et al., 2012). All tanks received recirculating water (pH 7 – 8 and conductivity 1000 μs) (Aleström et al., 2019). Zebrafish were fed a standard facility diet of Paramecium twice daily, up until 10 – 12 dpf, at which point they were weaned onto live Artemia (twice a day) and dried fish food (once a day). At 60 days post-fertilization (dpf), zebrafish were anesthetized in tricaine solution (4.2 ml of 0.4% in 100 ml of system water) and marked with Visible Implant Elastomer tags (VIE, Northwest Marine Technologies, Inc.; Shaw Island, Washington, United States) for individual identification. We used 9 colored tags: red, brown, purple, black, white, yellow, orange, pink,

164   green; and 'blank' (no marking). We injected fish once on either side of the dorsal fin (Hohn &
165   Petrie-Hanson, 2013), unless they were designated blanks. Zebrafish were marked in early
166   November 2019. We used a total of 160 WT zebrafish (n = 79 males, n = 81 females). All the
167   procedures involved in this experiment were approved by the Garvan Animal Ethics Committee
168   (approval: ARA 18_18).
169
170   *2.3 Testing apparatus*
171   We employed two different tank types (see Figure 1): trapezoidal tanks (width 11 cm, height
172   17.5 cm, length at top 28 cm, Figure 1B) and custom-designed tall tanks with increased depth
173   (width 7 cm, height 152 cm, length 10.5 cm, Figure 1A). Each tank had a standardized mark
174   displaying the water level at 3.4 L capacity.
175
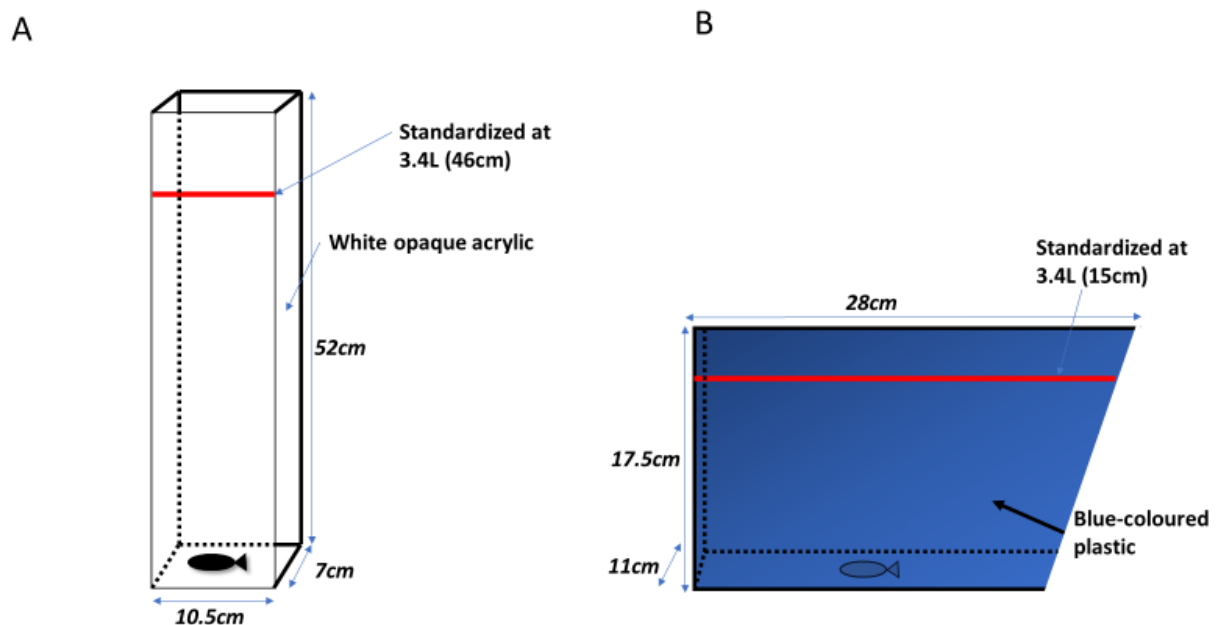

176
177   *Figure 1* **Characteristics of tanks used in anxiety assays.** A) Our custom-designed tall tank
178   was composed of white opaque acrylic on all sides except the front. The water depth was equated
179   to 46 cm after standardizing the volume of water at 3.4 L; B) Trapezoidal short tanks were
180   composed of blue-coloured transparent plastic.Water depth was equated to 15 cm when the
181   volume was standardized at 3.4 L (hence tanks did not differ in volume of water held).
182
183

2.4 Experimental setup

When using tall tanks, we set up 6 tanks to run 6 fish per trial. All 6 tanks were set side-by-side and facing the camera (Figure 2A). White Corflute® sheets were used to block all sides of the arenas except the front portion where the camera was placed; this ensured that fish were not disturbed during trials. When utilizing trapezoidal tanks, we set up 8 tanks to run 8 fish per trial. The setup for the trapezoidal tanks required the use of 2 cameras (4 tanks per camera). To fit 4 tanks in the frame of one camera, we placed a platform (raised approximately 25cm) behind two tanks to place an additional two tanks on top (Figure 2B). A white Corflute® sheet was also placed between the tanks (to prevent fish seeing each other) and behind (to improve contrast). We used the same setup on the other half of the main platform (a Corflute® sheet was placed between both setups). We labelled tanks appropriately with individual fish mark and tank ID.

A
B
Figure 2 **Setup of tall tanks and short tanks for anxiety assays.** A) Six tall tanks were positioned side-by-side on the main platform. Temporary holding containers were located directly behind each tank for ease of transfer of zebrafish as only one camera was used. No Corflute® was required owing to the opaque acrylic design of the side and back tank walls; B) Four short tanks were positioned in 2 by 2 setup (rows = 2, columns = 2). Those on the top row were placed on a raised custom-made platform. Those on the bottom row were placed directly in front of this platform. This allowed all 4 tanks to be captured in the camera frame. White Corflute® was placed between tanks to prevent fish from seeing each other, as well as behind tanks to improve contrast for video tracking. This same setup was also used on the other half of the main platform. Both halves of the platform were separated by Corflute®. We used 2 cameras to simultaneously capture 8 short tanks at once per trial; we labelled all tanks appropriately with individual fish mark and tank ID.

2.5 Experimental design and procedure

Anxiety assays began in early March 2020. Each individual experienced the anxiety assay in each type of tank twice (i.e. a fish was assayed 4 times in total). For each of the four assay sessions (the sessions were separated by 2 – 3 days), we tested all fish in a single day. We pseudorandomized the order of fish being tested to account for the day of experiments, as well as the time of day. In total, one assay consisted of 20 trials for short tanks (8 fish per trial) and 28 trials for tall tanks (6 fish per trial) (see Supplementary Material for more details). Before each trial, fish were removed from their holding tanks and isolated in separate containers (14 cm × 9 cm × 9 cm; 1.13L) for temporary holding (~5 mins). At the beginning of each assay, fish were transferred from their temporary holding container into their assigned testing tank (tanks 1 – 6 for tall tanks; tanks 1 – 8 for short tanks) and recorded for eight minutes, then removed. This continued until all fish had been assayed for the day. Trials began at 10 am and ended at 4 pm. Water changes occurred every hour to minimize drops in temperature (water was maintained at ~28°C) and the effects of stress hormones from fish already trialed (Pavlidis et al., 2013) (for more details, see the step-by-step protocol in Supplementary Materials).

2.6 Behavioral and statistical analyses

We analyzed all video recordings with the video tracking software Ethovision XT 14.0 (Noldus, Spink and Tegelenbosch, 2001). In Ethovision, we created three digital zones (low, mid and high; see Supplemental Materials Figures S4 and S5) in the tanks for analysis (see Ethovision protocol in Supplementary Materials). Acquisition of data began 40 seconds after the fish had been placed in the testing tank. This was deemed necessary as it took into account the time taken to place all fish in the testing tanks and ensured the lighting and contrast had stablised (changes occured once researchers removed themselves from the frame). We assessed anxiety by analyzing behavioral parameters as decided from our literature survey (see Results).

236
237 All statistical analyses were conducted in the R environment (Version 3.4.3) (R Development
238 Team, 2013) with R Studio (Version 1.1.453) (R Studio Team, 2015). To examine mean and
239 variance differences in anxiety-associated behaviour between tall and short tanks, we modelled
240 seven behavioral parameters: 1) time spent in the low zone, 2) time spent in the mid zone, 3)
241 time spent in the high zone; 4) latency to enter the high zone, 5) number of entries into the high
242 zone, 6) total distance travelled, and 7) time spent freezing, with thresholds at 0.25cm/s (start
243 velocity) and 0.10cm/s (stop velocity); see Results on how we chose these behavioral
244 parameters. We used linear mixed models implemented in the function *lme* in the *nlme* package
245 (version 3.1-148) (Pinheiro et al., 2020), which allowed us to model different residual variances.
246 We have used mixed-effects models as they are an overarching framework for ANOVA and t-
247 tests and allowed us to incorporate repeated measurements from the same individuals. This
248 approach has previously been recommended in the field of neuroscience (Aarts et al., 2014;
249 Boisgontier & Cheval, 2016; Shinichi Nakagawa & Hauber, 2011). In addition, mixed models
250 can deal with unequal measurements across individuals when there is missing data (Cnaan et al.,
251 1997). The residual normality of the behavioral measurements was visually checked for all
252 behavioral parameters. We applied transformations to three behavioral measurements to meet the
253 normality assumptions: square-root transformation on time spent in the high zone and entries
254 into the high zone, and ln-transformation on time spent freezing (after adding 1, because of 0
255 values); these transformed values were used throughout. In all mixed models (seven models; one
256 per behavioral measurement) we used tank type (i.e., our experimental condition) as a fixed
257 factor, as well as water condition (a temporal factor to control for fish being trialed in water that
258 had not yet been changed and therefore exposed to stress hormones from other fish). We used
259 fish ID as a random (clustering) factor. In addition, we also added sex as a fixed factor, as
260 behavioral responses often vary depending on sex (Michelangeli et al., 2016; Schuett et al.,
261 2010) and it is an important biological factor which improves reliability (Tannenbaum et al.,
262 2019). To model different residual variance between tall and short tanks, we specified an *lme*
263 function to do so, but also, we ran the same models assuming a constant variance between the
264 two types of tanks. These two models were compared by likelihood ratio tests using the *anova*
265 function from the R 'stats' package (Version 3.6.2) (R Core Team, 2013) to examine statistical
266 significance for modeling different variances.
267
268 Repeatability (R) is formally defined as the proportion of between-group (between-individual)
269 variance out of total variance (Sokal & Rohlf, 2012):
270
271 $$R = \frac{\sigma_\alpha^2}{\sigma_\alpha^2 + \sigma_\varepsilon^2}$$
272
273 where σ_α^2 is the between-group (between-individual) variance and σ_ε^2 is the within-group
274 (within-individual) variance. To calculate repeatability estimates between tall and short tanks,

275 and then between males and females in tall and short tanks, we used *rptR* (Version 0.9.21)
276 (Stoffel et al., 2017), a package based on a mixed-effects model framework using the R package
277 *lme4* (version 20) (Bates et al., 2014). Our repeatability analysis consisted of three steps. First,
278 the overall dataset was divided into tank subsets (i.e. short and tall) to obtain repeatability
279 estimates of each of the seven behavioral measurements with the *rpt* function. We also extracted
280 between-individual and within-individual variance estimates from *rptr* models after performing a
281 *z* transformation on response variables. Second, the dataset was further divided by sex to obtain
282 repeatability estimates of males and females in both tall and short tanks. All estimates were
283 'adjusted' repeatabilites (Nakagawa & Schielzeth, 2010), and included water condition as a fixed
284 factor and individual fish IDs as a random effect. We obtained standard error and 95%
285 confidence intervals (CIs) using *rptr*, which employs parametric bootstrapping (Faraway, 2016)
286 with all models set to have 10,000 bootstrap samples. Repeatability estimates with confidence
287 intervals not overlapping 0 were considered statistically significant. Third, we calculated
288 contrasts between repeatability estimates. We achieved this by calculating the differences
289 between estimated bootstrap distributions and obtaining quantiles at 2.5% and 97.5% from the
290 difference. Contrasts (subtracting a distribution with a higher mean from that with a lower mean)
291 were deemed significant if the difference distribution did not fall below the 2.5% threshold. All
292 R code and datasets are available at
293 https://github.com/Apex619/Tall_Tanks_Anxiety
294
295 ## 3. Results
296 *3. 1 Systematic survey*
297 From 336 studies identified from our literature search, we included 50 for analysis, following our
298 inclusion criteria (Table S8). These studies were published between the years 2008-2020,
299 comprised mainly of behavioral studies (44) with a few medical studies (5) and one toxicology
300 study. Regarding housing tanks used by studies in our sample, 12% housed zebrafish in small
301 tanks (~3-6L), 20% housed zebrafish in large tanks (~100-200L) and 42% housed zebrafish in
302 moderate tanks (~16-50L) (26% of studies did not specify housing tank sizes). Tank types
303 employed were either rectangular in shape (27) or trapezoidal (21), except for two studies (which
304 did not specify the shape). Mean dimensions for rectangular tanks were: height 20.1 cm ± 3.2
305 SD, width 12.6 cm ± 7.4 SD and length 23.6 cm ± 4.4 SD; and trapezoidal tanks were: height
306 15.6 cm ± 1.8 SD, width 7.4 cm ± 0.9 SD, length at bottom 22.8 cm ± 0.6 SD and length at top
307 27.8 cm ± 0.8 SD. Average sample sizes in studies equated to 14 ± 8.9 SD. We identified a total
308 of 16 behavioral parameters from included studies (see Figure 3) and tallied when they were
309 used in included studies. For analysis we used the 6 highly-ranked parameters along with one
310 parameter which was lowly ranked, but we felt was important to include (total of 7 parameters
311 shown in bold; see Figure 3).
312
313
314 *Figure 3* **Results from our systematic survey tallying behavioral parameters used in novel**
315 **tank test assays from the literature.** From our sample of 50 studies, we identified a total of 16
316 behavioral parameters used to assess an anxious state in novel tank tests. Of these 16 parameters,
317 we chose 7 (highlighted in bold). The first 6 ranked highest, i.e. were the most frequently used.
318 "Time spent in mid zone" was not amongst the most used parameters, however, we included it
319 based on our design of splitting the tank into 3 zones (as opposed to 2).
320
321
322
323
324

3.2 Behavioral parameter measurements

First, statistically significant differences were observed across all behavioral parameters across tank types (see Figure 4, Table S1). In short tanks, zebrafish travelled more (LMM, $est = 2,323.573$, $df = 469$, $t = 25.99$, $p < 0.001$); had longer bouts of freezing (LMM $est = 1.597$, $df = 469$, $t = 8.10$, $p < 0.001$) and spent more time in the low zone (LMM, $est = 328.927$, $df = 469$, $t = 33.34$, $p < 0.001$). In tall tanks, zebrafish spent more time in the mid zone (LMM, $est = 75.000$, $df = 469$, $t = 15.87$, $p < 0.001$) and high zone (LMM, $est = 8.505$, $df = 469$, $t = 18.14$, $p < 0.001$), displayed a quicker latency to enter the high zone (LMM, $est = 85.123$, $df = 469$, $t = 6.36$, $p < 0.001$) and recorded more entries into the high zone (LMM, $est = 4.365$, $df = 469$, $t = 16.61$, $p < 0.001$). Mean responses between sexes did not significantly differ except for the latency to enter the high zone (see Table S1). Water condition had no significant influence on behavioral parameters except for time spent in the low zone and latency to the high zone (see Table S1). Second, tall tanks generated more overall variation than short tanks for time spent in the low zone (6.71%, $p < 0.001$), mid zone (4.47 %, p 0.007) and high zone (6.24%, $p < 0.0001$) as well as entries into the high zone (5.66%, $p < 0.0001$). Time spent freezing however, was more variable in short tanks (4.24%, p 0.0117). No statistically significant differences in variance were observed between tall and short tanks for total distance travelled and latency to the high zone (Figure 4).
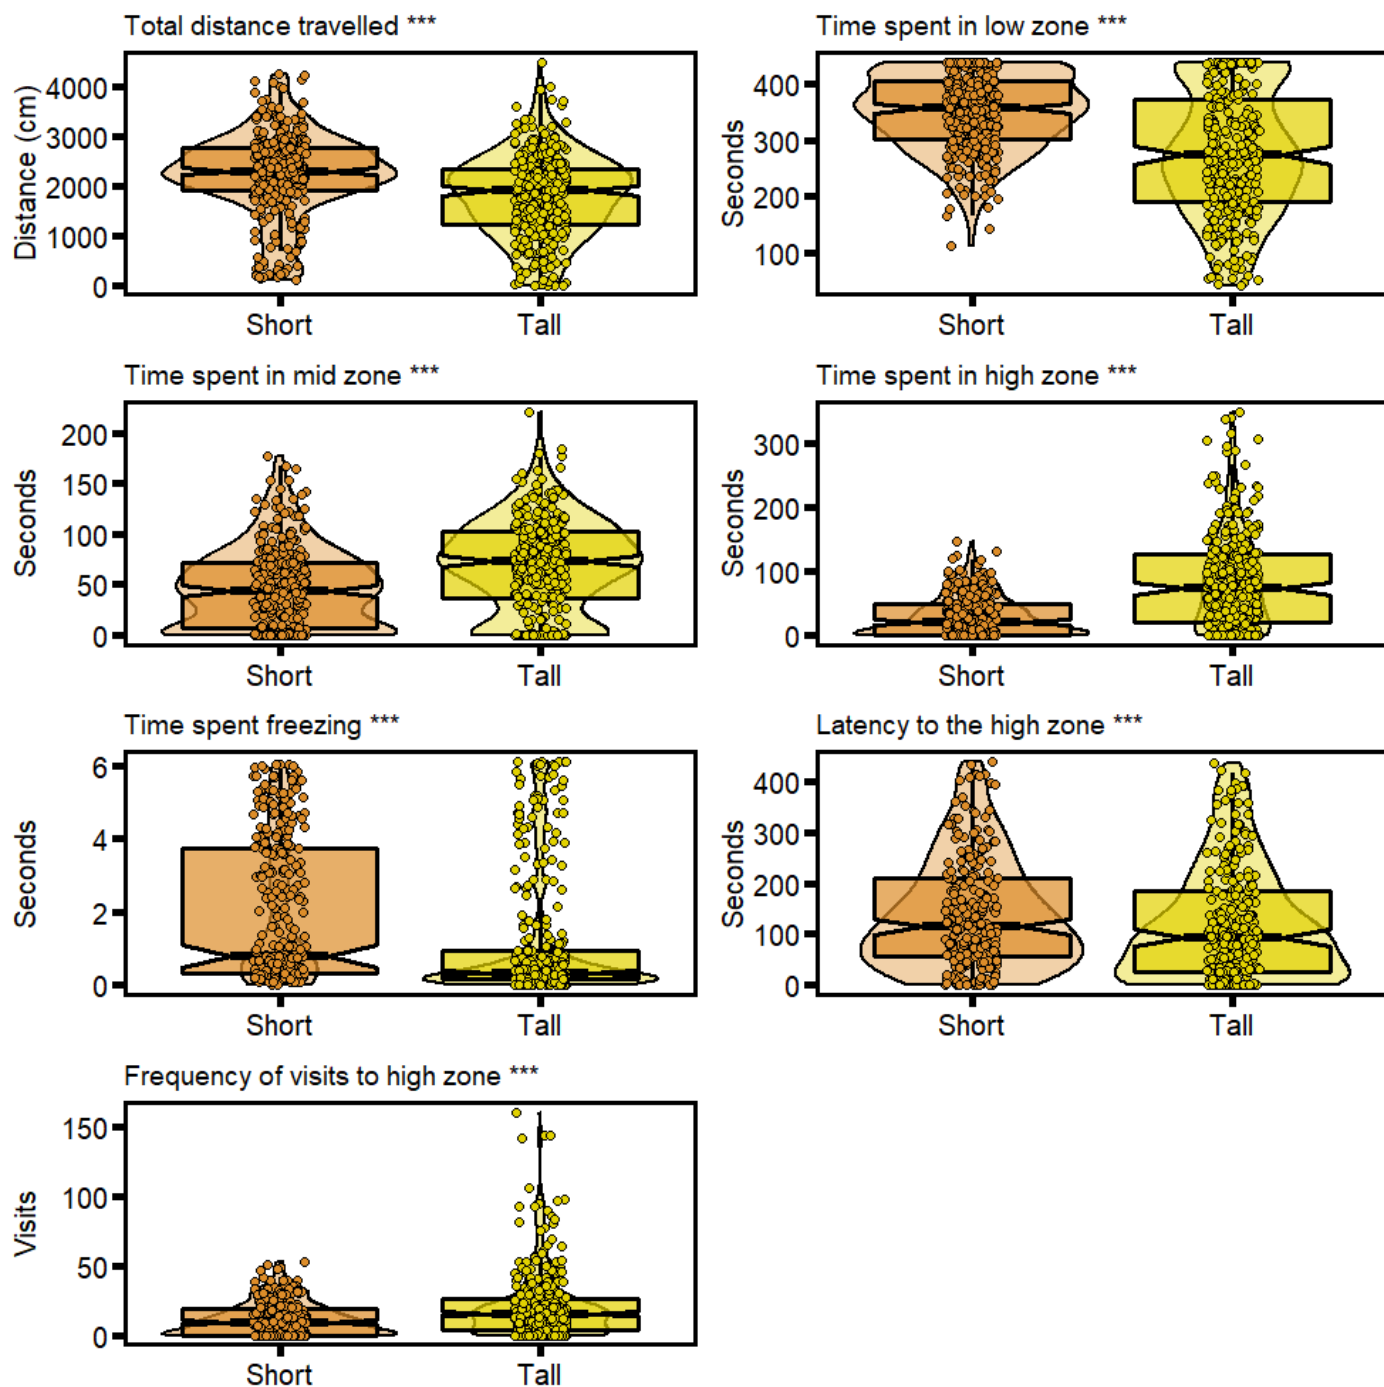

343
344 *Figure 4* **Distribution of zebrafish behavioral measurements in short and tall tanks.** Each
345 plot displays a combination of: individual data points for males (n = 79) and females (n = 81)
346 from two observations in different tanks (total of 320 observations per plot). Box plots show the
347 median, 95% confidence interval of the median, quantiles and outliers. Violin plots display
348 distribution density. Time spent freezing is transformed using log(x+1) function. Note: ***p<0.01
349
350

3.3 Repeatability analysis

351

352 Overall, repeatability estimates were in the expected direction, with tall tanks having higher
353 repeatability than short tanks for 5 out of 7 analysed behavioral parameters (see Figure 5; Table
354 S2): total distance travelled ($R = 0.42$, 95% CI [0.28 – 0.54]), time spent in the low zone ($R =$
355 0.55, 95% CI [0.43 – 0.65]), time spent in the high zone ($R = 0.60$, 95% CI [0.49 – 0.69]),
356 latency to the high zone ($R = 0.49$, 95% CI [0.35 – 0.62]) and time spent freezing ($R = 0.32$, 95%
357 CI [0.18 – 0.45]). However, for only 2 out of these 5 parameters was the difference between tall
358 and short tanks statistically significant: time spent in the low zone (95% CI [0.02 – 0.37]) and
359 latency to the high zone (95% CI [0.13 – 0.58]). Males had higher repeatability estimates than
360 females for all measured behavioural parameters, displaying a clear sex difference (see Figure 6;
361 Table S4). Except for the total distance travelled and time spent freezing, all repeatability
362 estimates in tall tanks were significantly different between males and females.

363

364 Short tanks had higher and statistically significant repeatability estimates only for time spent in
365 the mid zone ($R = 0.51$, 95% CI [0.38 – 0.62]) and entries into the high zone ($R = 0.48$, 95% CI
366 [0.35 – 0.59]). Results for sex differences were mixed in short tanks (see Figure 7; Table S3).
367 Males had higher repeatability than females for total distance travelled, time spent in the mid
368 zone, and time spent freezing. However, females had higher repeatability than males for time
369 spent in the low zone, time spent in the high zone and entries into the high zone. Repeatability
370 estimates for latency to the high zone in short tanks were statistically non-significant. Unlike in
371 the tall tanks, we only found statistically significant differences between males and females in
372 short tanks for total distance travelled (95% CI [0.38 – 0.70]) and time spent freezing (95% CI
373 [0.03 – 0.56]).

374
375
376 *Figure 5* **Forest plot of repeatability estimates for each measured behavioral parameter in**
377 **tall (yellow) and short tanks (orange), as well as their contrast (in black).** Repeatability
378 estimates are deemed significant if the associated 95% confidence interval does not cross 0. The
379 contrasts are deemed significant (denoted by *) if the associated confidence interval does not
380 cross 0.
381

Figure 6 **Forest plot of repeatability estimates for males (blue) and females (red) , as well as the contrast between the sexes (in black), per behavioral parameter in tall and short tanks.** Repeatability estimates are deemed significant if the associated 95% confidence interval does not cross 0. The contrasts are deemed significant (denoted by *) if the associated confidence interval does not cross 0.

4. Discussion

The main goal of this study was to design an efficient anxiety assay that better captures between-individual variation. To do so, we compared the repeatability of behavior in anxiety tank tests between custom-designed tall tanks and short trapezoidal tanks. We addressed three specific aims in this study. First, we mapped a sample of the relevant literature, which confirmed our assumption that studies employ tanks that have a limited depth. Second, we compared anxiety-related behavioral parameters in zebrafish between the two types of tanks, which showed clear behavioral differences. Third, we hypothesized that using the tall tanks would lead to higher repeatability estimates than short tanks. On average, our tall tanks generated more behavioural variation, had higher repeatability estimates and displayed clearer effects between sexes when comparing repeatability estimates. We discuss each of these three points in more detail below.

4.1 Anxiety literature survey

Our survey showed that tanks with depths similar to our tall tanks are not used in novel tank test assays. Although we expected this survey result, it is still somewhat surprising for two reasons. First, when evaluating anxiety, depth is a significant factor in influencing zebrafish behavioral responses (Blaser & Rosemberg, 2012; Córdova et al., 2016; Kysil et al., 2017). Second, anxious zebrafish show a tendency to dive in novel environments (Levin et al., 2007). This diving response indicates a preference to escape the water surface, rather than to simply approach the bottom of a tank (Kysil et al., 2017), emphasizing depth preference. The average heights of tanks used in studies surveyed ranged from 16 to 20 cm (similar to our short tanks which was 17.5cm in height), which may be inadequate in capturing between-individual variation.

4.2 Behavioral response differences

Our analysis revealed that zebrafish in the short tank travelled more and displayed longer bouts of freezing, although both types of tanks had the same volume of water. Total distance travelled may be directly associated with the dimensions of the trapezoidal (short) tank. That is, while shorter in height, the trapezoidal tanks are also much longer in length in comparison to our tall tanks, allowing fish to swim horizontally in the trapezoidal tanks compared to the tall tanks, which limit the fishes' horizontal movements. As such, zebrafish might have adjusted their locomotion to suit this environment (i.e. the tall tank) (Stewart et al., 2012). Furthermore, longer bouts of freezing in short tanks may be the result of a sudden change in social dynamics, as our short testing tanks were the same as those used to house zebrafish in groups (i.e. the novelty may mainly come from social environment disruption rather than the tank itself). Therefore, tanks similar to holding tanks are likely to affect behavioral responses (Bencan et al., 2009).

Overall, we attribute zebrafish behavioral responses to dimensional differences between tall and short tanks. For example, the vertical nature of the tall tank, which had a limited width for horizontal movement, may have driven zebrafish to explore the mid zone and high zone in the tall tank more than in the short tank. As expected, tall tanks also generated more overall

430 behavioral variation than short tanks. This increased variation likely led to enhanced between-
431 individual variation and, consequently, repeatability (see below).
432
433 *4.3 Repeatability*
434 Overall, we demonstrated that, regardless of tank depths, almost all behavioral parameters
435 associated with anxiety in zebrafish were significantly repeatable in novel tank tests ($R = 0.23$ to
436 0.60; Figure 5). This result follows suit with a recent study showing significant repeatability in
437 behavioral responses from novel tank tests in zebrafish ($R = 0.35$ to 0.47 for the parameters total
438 distance travelled, time spent in bottom zone, time spent freezing and exploration; Thomson et
439 al., 2020). Indeed, our tall tanks are also better at characterizing between-individual differences
440 by increasing between-individual variation or decreasing within-individual variance (see Figures
441 S1, S2, S3; and Table S2), which results in higher repeatability estimates (tall tanks: $R = 0.30$ to
442 0.60; short tanks: $R = 0.10$ to 0.53; Figure 5).
443
444 Differences in repeatability resulting from the use of tall tanks may have important implications
445 in (bio-)medical science. We argue that seeing too little variation hinders the ability of
446 researchers to make accurate conclusions, for instance regarding treatment efficacy (Senior et al.,
447 2016). Further, identifying and understanding sources of variation is considered necessary to
448 better discern observed responses and better cater treatments at the individual level as opposed to
449 the population level (Braga & Panteghini, 2016; Senn, 2016). More importantly, our new assay,
450 which has higher repeatability, could be more effective in distinguishing effects between control
451 and treatment groups than assays that have lower repeatability (e.g., Mizuno et al., 2020).
452 Essentially, accurately capturing between-individual variation should translate into more
453 accurate capturing of between-group/treatment variation (Fisher et al., 2018). Furthermore, our
454 result highlight the importance of employing methods that ensure behavioral responses are
455 specific to the assumptions of the paradigm being measured, i.e. construct validity (Giuliano et
456 al., 2008; Liu et al., 1982; Maximino et al., 2010). Assays that are usually believed to be
457 appropriate and effective may lack the components needed to detect subtle, yet important,
458 information – including between-individual variation (like what we have shown between
459 conventional short tanks and our custom-designed tall tank).
460
461 Our finding also has implications for animal personality studies. Consistent individual
462 differences in behavior (and therefore repeatability) are an essential component of 'animal
463 personality' (Dall et al., 2004). Consistent individual differences may represent adaptive
464 behavioral differences within a group (Dall et al., 2004), which, in turn, can influence individual
465 fitness (Dingemanse & Réale, 2005; MacPherson et al., 2017). For example, an animal's
466 inclination to take risks is associated with the bold-shy behavioral continuum (Sloan Wilson et
467 al., 1994), that is closely related to anxiety (Koolhaas et al., 1999). In novel tank test assays, bold
468 individuals (less anxious) are likely to travel more and traverse to the upper regions of the tank.
469 In our assay, tall tanks captured between-individual variation in behavioral parameters related to

470 total distance travelled and time spent in the low zone better than short tanks (See Figure 5). As
471 previously highlighted, the methodology becomes crucial when attempting to capture between-
472 individual variation.
473
474 There seems little emphasis on employing diverse methods to quantify and compare
475 repeatabilities. As such, we call for investing time into comparing and contrasting different
476 assays (e.g., O'Neill et al., 2018) to find the one that is most relevant to the question at hand
477 (note that the most relevant method may not always have the highest repeatability). For example,
478 one way of improving methodology is to assess the ecological relevance of the trait being
479 measured for the species being measured (Roche et al., 2016) (i.e. depth preference in zebrafish,
480 which is better captured by the use of a deeper tank).
481
482 We also found significant sex differences in tall tanks, with males displaying more consistent
483 responses than females for all behavioral parameters (tall tanks males: $R = 0.31$ to 0.69; tall tanks
484 females: $R = 0.12$ to 0.49), mimicking results found by Thomson et al. (2020) (males: $R = 0.45$ to
485 0.58; females: $R = 0.15$ to 0.24). In contrast, results for sexes were mixed in short tanks.
486 Behavioural repeatability was low in females for 3 out of 7 parameters, and there was no clear
487 pattern observed (i.e. one sex being more consistent than the other). However, of the 2
488 statistically significant results obtained (total distance travelled and time spent freezing), males
489 still displayed higher repeatability than females, a trend also observed in other behavioral studies
490 with different animal models (e.g., Strickland & Frère, 2018; Wexler et al., 2016). Thus, we
491 confirmed the inclusion of sex as an important biological factor to disentangle sources of
492 variation.
493

494 *4.4 Limitations and future directions*
495 Our improved assay follows the traditional novel tank test. This method relies on zebrafish
496 responding to an unfamiliar environment. However, our assay involved repeated tests in the
497 same tanks making it challenging to maintain tank novelty following the initial assay. This was
498 unavoidable as we aimed to calculate repeatability estimates which required a minimum of 2
499 measurements. We attempted to ensure that subsequent assays maintained a novelty aspect by 1)
500 having sufficient gaps in between assays (2-3 days) and 2) following a pseudorandomized
501 schedule for the type of tank used (i.e., Day 1 tall tank, Day 2 short tank, Day 3 tall tank, Day 4
502 short tank). Regardless, we believe the novelty aspect is also caused by a sudden change in social
503 environment (fish are usually housed in groups but then suddenly isolated before and during the
504 assay).
505
506 In terms of repeatability, our tall tanks displayed better estimates of repeatability, paving the way
507 for future research to potentially employ our methods. In saying so, our study tested individuals
508 in each tank twice (a total of four assays) over one week (with $2 - 3$ days between each assay).
509 However, recent research has highlighted that more tests carried out over an extended period

510 would increase the accuracy of measurements (Thomson et al., 2020). This approach will also
511 address issues associated with observations taken closely together in time, an action which can
512 overestimate repeatability (Mitchell et al., 2020).
513
514 Further, our research compared short tanks to custom-designed tall tanks with different
515 dimensions. As such, we did not investigate a 'truer' comparison which would have involved
516 comparing short tanks to tanks with identical X-Y dimensions, but with the added feature of
517 increased depth. Our approach was intentional because it provided much greater efficiency given
518 that we were able to film multiple fish at once. In addition, our study would have been
519 confounded due to differences in water volume. Another major strength of our study was our
520 large sample size (79 males and 81 females) in comparison to most studies, enabling us to draw
521 more robust conclusions. However, to ensure all fish were assayed in one day, we employed
522 water changes on an hourly basis rather than a trial-by-trial basis. This would have resulted in
523 some fish being exposed to stress hormones from earlier fish until the water had been changed.
524 To account for this, we included water condition as a factor in our statistical models. While water
525 condition did not significantly influence zebrafish behavioral responses (aside from time spent in
526 the low zone and latency to the high zone), the direction of these responses was biologically
527 consistent with stress. We implore future studies to change water on a trial-by-trial basis or
528 statistically control for water condition to avoid confounds.
529
530 In conclusion, our study implemented a custom-designed tall tank to measure zebrafish anxiety
531 in novel tank tests. In doing so, we developed an efficient new assay that captured more
532 between-individual variation, and consequently, repeatability, an important index that improves
533 the reliability of experimental data (Branch, 2019; Hopkins, 2000; Vaz et al., 2013). Also, our
534 tall-tank assay is advantageous in the sense that many studies conducting zebrafish novel tank
535 tests use tanks with limited depth, ranging from ~15-20 cm, whereas our tanks are 46cm deep .
536 Further, our tall-tank assay with increased depth was able to effectively detect sex differences in
537 comparison to our short-tank assay. We highly recommend employing this newly developed
538 assay in anxiety diving tests to improve reliability of behavioral data amongst future studies in
539 (bio-)medical and behavioral sciences.
