3 1 **LAY SUMMARY**
4

5 2 In some group-living species, individuals divide into subgroups to minimize feeding
6
7 3 competition, which can reduce social opportunities. Bonobos and chimpanzees exhibit such
8
9 4 dynamics, but chimpanzees face higher feeding competition and can spend substantial time
10
11 5 feeding alone. Despite this difference in grouping, females of the two species spend similar
12
13 6 amounts of time engaged in social interactions.

34

35 15 Fission-fusion dynamics have evolved in a broad range of animal taxa and are thought to allow
36
37 16 individuals to mitigate feeding competition. While this is the principal benefit of fission-fusion,
38
39 17 few studies have evaluated its costs. We compared gregariousness, foraging budgets, and social
40
41 18 budgets between lactating bonobos and chimpanzees from wild populations to evaluate such
42
43 19 costs. Both species exhibit fission-fusion dynamics, but chimpanzees, particularly in East
44
45 20 African populations, appear to experience higher feeding competition than bonobos. We
46
47 21 expected lactating chimpanzees to be less gregarious than lactating bonobos; reduced
48
49 22 gregariousness should allow lactating chimpanzees to mitigate costs of higher feeding
50
51 23 competition without requiring more foraging effort. However, we expected the reduced
52
53

57
58
59
60

1
2
3 24 gregariousness of lactating chimpanzees to limit their time available for affiliative social
4
5 25 interactions. Using long-term data from LuiKotale bonobos and Gombe chimpanzees, we found
6
7 26 that lactating chimpanzees were indeed less gregarious than lactating bonobos although feeding
8
9 27 and travel time did not differ between species. Contrary to our predictions, lactating females did
10
11 28 not differ in social interaction time, and lactating chimpanzees spent proportionately more time
12
13 29 interacting with individuals other than their immature offspring. Our results indicate that
14
15 30 lactating chimpanzees can maintain social budgets comparable to lactating bonobos despite
16
17 31 reduced gregariousness and without incurring additional foraging costs. We discuss explanations
18
19 32 for why lactating bonobos are more gregarious.

47 INTRODUCTION

48 A major goal in the study of behavioral ecology is to understand the evolution of group living
49 under different ecological conditions (Wilson 1975; Maynard Smith and Szathmary 1997).

50 Extensive research demonstrates that one of the primary benefits of group living is enhanced
51 predator detection, dilution, and/or defense capabilities, while one of the major costs of group
52 living is increased competition for food resources (reviewed in Ward and Webster 2016). Costs
53 associated with feeding competition are particularly salient to females, given that food generally
54 limits female reproductive success more so than males' (Trivers 1972).

55
56 Due to intragroup feeding competition, foraging effort is a function of group size: individuals
57 living in permanently cohesive social groups experience reduced feeding efficiency as the
58 number of intragroup competitors increases (Beauchamp 2012; Markham et al. 2015). Therefore,
59 females in many social species cope with the high energetic requirements of lactation principally
60 by allocating more time to foraging effort (*Lasiurus cinereus*: Barclay 1989; *Peromyscus*
61 *maniculatus*: Hammond and Kristan 2000; *Odocoileus virginianus*: Therrien et al. 2008; *Myotis*
62 *lucifugus*: Dzal and Brigham 2013; *Enhydra lutris nereis*: Thometz et al. 2016). However, any
63 increase in time dedicated to foraging effort must come at the expense of time allocated to other
64 activities (Dunbar et al. 2009), as is the case in numerous vertebrate taxa (e.g., *Octodon degus*:
65 Ebensperger and Hurtado 2005; *Oreamnos americanus*: Hamel and Côté 2008; *Rhinopithecus*
66 *bieti*: Xiang et al. 2010; *Morus capensis*: Rishworth et al. 2014). One activity that may be
67 sacrificed to provide more time for foraging is affiliative social interactions; however, such
68 interactions play an important role in maintaining social bonds in many group living animals.
69 Indeed, a growing body of research highlights the positive relationship between social bond

1
2
3 70 strength and fitness across taxa (e.g., *Papio cynocephalus*: Silk et al. 2003; *Equus ferus caballus*:
4
5 71 Cameron et al. 2009; *Tursiops aduncus*: Stanton and Mann 2012; *Crotophaga major*: Riehl and
6
7 72 Strong 2018). Thus, sacrificing time for social interactions may carry costs in some taxa.
8
9

10 73
11
12 74 Fission-fusion social systems present additional means through which lactating females may
13
14 75 mitigate feeding competition. Fission-fusion societies are characterized by fluid subgrouping
15
16 76 patterns (Aureli et al. 2008) and have been described for diverse taxa (Couzin 2006), such as
17
18 77 guppy shoals (*Poecilia reticulata*) (Kelley et al. 2011), sand tiger sharks (*Carcharias taurus*)
19
20 78 (Haulsee et al. 2016), common ravens (*Corvus corax*) (Loretto et al., 2017), African lions
21
22 79 (*Panthera leo*) (Mbizah et al. 2019), and Cape buffalo (*Syncerus caffer caffer*) (Wielgus et al.
23
24 80 2020). High fission-fusion dynamics are hypothesized to allow individuals to adjust subgroup
25
26 81 size and composition in response to fluctuations in food availability and their own energetic
27
28 82 requirements. Thus, females can mitigate the energetic costs of lactation by altering their
29
30 83 grouping patterns to maintain energy balance without substantial increases in foraging effort,
31
32 84 while also grouping when possible to maximize predator defense and social opportunities.
33
34 85 However, this raises the question of whether fission-fusion dynamics impact the extent to which
35
36 86 lactating females suffer from increased predation and/or reduced social interactions. By ranging
37
38 87 alone or in smaller subgroups, lactating females may not need to increase foraging effort, but
39
40 88 they may be more vulnerable to predators and/or their social activity may be constrained as a
41
42 89 result of spending less time in the presence of group members.
43
44
45
46
47
48

49 90
50
51 91 The genus *Pan* provides a comparative framework through which to focus on the social costs of
52
53 92 fission-fusion dynamics while discounting potential effects of predation risk. The two great ape
54
55
56
57
58
59
60

1
2
3 93 species that comprise *Pan*, bonobos (*P. paniscus*) and chimpanzees (*P. troglodytes*), share a
4
5 94 recent phylogenetic history (Prüfer et al. 2012) and several core morphological and behavioral
6
7
8 95 traits. In particular, both species are characterized by a relatively large body size relative to most
9
10 96 other primate species, as well as a largely arboreal lifestyle (Fleagle 2013); these traits are
11
12 97 hypothesized to reduce vulnerability to their most likely predator, African leopards (*Panthera*
13
14 98 *pardus pardus*) (Isbell 1994; Janson and Goldsmith 1995; Zuberbühler and Jenny 2002). Indeed,
15
16
17 99 evidence for leopard predation on bonobos and chimpanzees is rare (for all inferred cases of
18
19 100 leopard predation in *Pan*, see: Boesch 1991; Furuichi 2000; Zuberbühler and Jenny 2002;
20
21 101 D'Amour et al. 2006; Pierce 2009; Nakazawa et al. 2013), despite extensive evidence of leopard
22
23 102 predation on monkeys (reviewed in Isbell 1994) including at study sites where leopard predation
24
25
26 103 on chimpanzees has been documented and deemed rare (e.g., Nakazawa 2020).

27
28 104
29
30
31 105 Despite broad similarities in morphology and social organization between bonobos and
32
33 106 chimpanzees, they appear to face different levels of feeding competition and starkly different
34
35 107 patterns of female social behavior (reviewed in Gruber and Clay 2016). Stable isotope analyses
36
37 108 of hair samples from multiple *Pan* research sites across tropical Africa indicate clear species
38
39 109 differences in the stability of food resources (Oelze, Fahy, et al. 2016). Stable isotope ratios
40
41 110 provide a reliable proxy for diet because the isotopic characteristics of food components are
42
43 111 incorporated into consumers' tissue in a predictable manner (Kohn 1999). Bonobos exhibit less
44
45 112 variation in stable isotope ratios over time when compared to chimpanzees, indicating that
46
47 113 bonobo diet composition is more stable, i.e., less seasonal, than that of chimpanzees (Oelze,
48
49 114 Douglas, et al. 2016; Oelze, Fahy, et al., 2016). Additionally, individual variation in females'
50
51
52
53 115 stable isotope ratios did not vary based on dominance rank in bonobos (Oelze, Douglas, et al.

1
2
3 116 2016), whereas several studies have demonstrated variation in diet quality based on dominance
4
5 117 rank in chimpanzees (e.g., Murray et al. 2006). These patterns strongly suggest that feeding
6
7 118 competition is more intense in chimpanzees than in bonobos.
8
9
10 119
11
12 120 Reduced feeding competition among female bonobos may facilitate what appears to be a general
13
14 121 pattern of high female gregariousness across several long-term study sites (Wamba: Furuichi
15
16 122 2009; LuiKotale: Moscovice et al. 2017; Lomako: Hohmann and Fruth 2002; Waller 2011). This
17
18 123 high gregariousness may in turn facilitate the high degrees of intrasexual affiliative social
19
20 124 behavior characteristic of female bonobos (Tokuyama and Furuichi 2016; Moscovice et al. 2017,
21
22 125 2019). In contrast, female gregariousness varies across chimpanzee populations. Females in
23
24 126 some East African chimpanzee populations (*P. t. schweinfurthii*) tend to be highly solitary,
25
26 127 frequently ranging alone with their immature offspring in order to mitigate costs associated with
27
28 128 exceptionally high feeding competition and seasonality (Wrangham and Smuts 1980). In other
29
30 129 East African chimpanzee populations, females can be more gregarious (Wakefield 2008). Some
31
32 130 female West African chimpanzee populations (*P. t. verus*) appear to experience reduced
33
34 131 seasonality when compared to East African chimpanzees (Doran et al. 2002) and are more
35
36 132 gregarious (Lehmann and Boesch 2008, 2009). What remains unclear is whether different
37
38 133 patterns of fission-fusion dynamics differentially constrain the extent to which females can
39
40 134 engage in affiliative social interactions because direct comparisons of gregariousness and social
41
42 135 budgets have not been conducted in the two *Pan* species. While a study evaluating within-
43
44 136 population variation in dyadic association strength across *Pan* populations found clear species
45
46 137 differences that are in line with putative species differences in gregariousness, they did not make
47
48 138 direct comparisons between the populations (Surbeck et al. 2017).
49

1
2
3 139
4
5
6 140 In this study, we compared gregariousness, foraging budgets, and social budgets of lactating
7
8 141 females in wild populations of bonobos and chimpanzees. The lactation period represents the
9
10 142 female life history stage when energetic demands are highest and thus when constraints on social
11
12 143 interactions should be most pronounced. Here we compared the LuiKotale bonobo population to
13
14 144 the Gombe East African chimpanzee population. LuiKotale is characterized by low seasonality,
15
16
17 145 extensive primary forest, and modest resource competition (Hohmann et al. 2012; Oelze,
18
19 146 Douglas, et al. 2016; Oelze, Fahy, et al. 2016; Nurmi et al. 2018), while Gombe appears to be
20
21
22 147 characterized by high seasonality and heterogeneity in habitat structure (Wrangham and Smuts
23
24 148 1980; Williams et al. 2002; Murray et al. 2006). We hypothesized that lactating chimpanzees at
25
26 149 Gombe are less gregarious than lactating bonobos at LuiKotale due to higher feeding
27
28
29 150 competition at Gombe. We further predict that reduced gregariousness constrains the social
30
31 151 interaction budgets of lactating chimpanzees; while being less gregarious may allow lactating
32
33 152 chimpanzees to maximize foraging efficiency, they may then be limited in the extent to which
34
35 153 they can engage in social interactions. Based on this hypothesis, we predicted that the amount of
36
37
38 154 time that lactating females spend engaged in feeding and travel does not differ between species,
39
40 155 but that lactating chimpanzees spend less time in groups and less time engaged in affiliative
41
42
43 156 social interactions. We first compared gregariousness by evaluating the proportion of time that
44
45 157 lactating females spend ranging alone with their immature offspring. We then compared the
46
47 158 amount of time that lactating females spend engaged in feeding, travel, and affiliative social
48
49 159 interactions, and how lactating females allocate their affiliative social interactions.
50

51 160

54 161 **MATERIALS AND METHODS**

162 **Study site and subjects**

163 Data were collected on the Bompusa West bonobo community at LuiKotale, Democratic
164 Republic of the Congo, and on the Kasekela chimpanzee community at Gombe, Tanzania. All
165 bonobos and chimpanzees included in our study were habituated to human observation. Maternal
166 relatedness is known for all individuals from observations and genotyping. During the study
167 periods, the Bompusa West community included up to 54 individuals and the Kasekela
168 community included up to 68 individuals. We focused our analyses on lactating females whose
169 youngest infants were less than 4.5 years of age as this is the average age by which infants in
170 wild populations of both species are nutritionally weaned based on stable isotope analyses (~4
171 years based on $\delta^{15}\text{N}$ and ~5 years based on $\delta^{13}\text{C}$ in both species: Ngogo chimpanzees: Bădescu et
172 al. 2017; LuiKotale bonobos: Oelze et al. 2020). This age range also overlaps with the average
173 weaned age derived from data on suckling behavior in our chimpanzee study population (4.7
174 years: (Lonsdorf et al. 2020). We used approximate periods of lactation because precise ages of
175 weaning are likely to vary (e.g., Borries et al. 2014) and are not known for the majority of
176 individuals in our sample. We pooled data on lactating females into three age classes based on
177 the age of their youngest infant ($0 < 1.5$, $1.5 < 3$, and $3 < 4.5$ years), given that lactating female
178 energetic requirements may vary based on stage of infant development (see Emery Thompson et
179 al. 2012).

180

181 **Predictions**

182 We tested three predictions: 1) Lactating chimpanzees spend more time alone with their
183 immature offspring than do lactating bonobos; 2) Lactating females of the two species do not

1
2
3 184 differ in feeding or travel time; 3) Lactating bonobos spend more time engaged in social
4
5 185 interactions, particularly with individuals other than their immature offspring.
6
7
8 186

9
10 187 **Time spent alone**

11
12 188 At both study sites, the total number of individuals ranging in subgroups (hereafter “parties”) and
13
14 189 their identities are recorded systematically. Party scan data on lactating females are recorded
15
16
17 190 during focal follows (see next section for a description of focal follows) at regular intervals and
18
19 191 represent all individuals observed in the party during that interval; researchers record party scans
20
21 192 every hour at LuiKotale and every 15 minutes at Gombe. To make party scan data comparable
22
23
24 193 between sites, we aggregated all party scans over a given hour at Gombe and used the aggregated
25
26 194 on-the-hour party scan in our analyses. We only included lactating females for which at least 20
27
28 195 hours of party scans were available for a given infant age class (Table 1). We took several
29
30 196 additional steps to ensure that data from both study sites are comparable. First, we used
31
32
33 197 contemporaneous data from both sites, starting in July 2011, when two coauthors (CMM and
34
35 198 EVL) hired several new field staff to collect data at Gombe and conducted extensive training to
36
37
38 199 ensure that data collection remained consistent despite a change in field staff. Long-term party
39
40 200 scan data were available from LuiKotale for the same period. We thus included party scan data
41
42 201 from July 2011 through November 2016 for both study sites. Second, because the Gombe party
43
44 202 scan dataset is larger than the LuiKotale dataset due to more field researchers collecting data at
45
46
47 203 Gombe, we used the sample function in base R version 4.0.2 (R Core Team 2020) to randomly
48
49 204 subsample on-the-hour party scans from Gombe without replacement to match the LuiKotale
50
51 205 party scan sample size, based on number of lactating females, infant sex, and infant age class.
52
53
54 206 For example, if we had 10 total on-the-hour party scans from two lactating bonobos, each with
55
56
57
58
59
60

1
2
3 207 one female infant in the $0 < 1.5$ infant age class, we subsampled the Gombe data such that we
4
5 208 had approximately 10 total on-the-hour party scans from two lactating chimpanzees, each with
6
7
8 209 one female infant in the $0 < 1.5$ infant age class.
9

10 210

11
12 211 We measured gregariousness of lactating females as the proportion of party scans in which the
13
14 212 lactating female was alone with her immature offspring, which we defined as offspring younger
15
16
17 213 than 12 years of age. This definition for immature offspring is consistent with previous research
18
19 214 on both of our study populations (e.g., Murray et al. 2006; Surbeck et al. 2011; Stanton et al.
20
21 215 2014; Markham et al. 2015) and a recent study indicating that chimpanzee offspring continue to
22
23 216 associate with their mothers until 12 years of age (Stanton et al. 2020). We do not claim that 12
24
25 217 years of age and older qualifies as adult; rather, individuals below this age are predominantly
26
27 218 immature. Thus, when a focal subject is alone with her immature offspring, i.e., not in a party
28
29 219 with other community members, we considered her to be “alone” in her own focal follow.
30

31
32
33 220 Researchers attempt to remain with the focal subject at both study sites, regardless of party size.
34

35 221

36 222 **Feeding, travel, and social interactions**

37
38 223 In addition to party scan data, researchers collect detailed behavioral data during focal follows of
39
40 224 a lactating female and her immature offspring. At Gombe, a given focal follow focuses on a
41
42 225 lactating female and her two youngest offspring simultaneously and lasts from several hours to a
43
44
45 226 full day; the goal is to collect at least six hours of focal follow data on each focal subject during
46
47 227 each month. However, focal follow lengths vary based on various uncontrollable factors such as
48
49 228 losing sight of the focal subject during poor weather conditions. At LuiKotale, a given focal
50
51 229 follow focuses on a lactating female and one of her immature offspring at a time and are
52
53
54
55
56
57
58
59
60

1
2
3 230 generally conducted for one hour. Focal follows can be longer if the focal subject is alone with
4
5 231 her immature offspring because researchers generally attempt to follow lone focal females
6
7
8 232 continuously until she rejoins a larger party. These differences in focal follow duration and the
9
10 233 number of immature offspring on which data are collected are due to practical constraints
11
12 234 associated with focal following two immature bonobos simultaneously for extended durations,
13
14 235 given that there are generally many immature bonobos present in parties and it can be very
15
16
17 236 difficult to monitor multiple at once. However, to ensure consistency in our comparative
18
19 237 analyses, the behavioral ethogram in place at LuiKotale was developed in collaboration with
20
21 238 Gombe researchers and designed to be comparable by utilizing the same definitions for all
22
23
24 239 behaviors of interest and by employing the same point sampling interval; behavioral data on the
25
26 240 lactating female and her immature offspring are recorded during one-minute point samples and
27
28 241 include the identity of social partners.
29

30 242
31
32
33 243 Despite using the Gombe protocol as a model to design the protocol at LuiKotale, we took
34
35 244 additional steps to ensure that data are comparable between the two study sites. Focal follow data
36
37 245 on bonobos were collected between July 2015 and July 2018; however, chimpanzee focal follow
38
39
40 246 data were only available through November 2016. We thus utilized focal follow data on
41
42 247 chimpanzees between November 2013 and November 2016 to match the number of years during
43
44 248 which bonobo data were collected. Second, we again subsampled the larger Gombe dataset to
45
46
47 249 approximately match the LuiKotale sample size, again using the sample function in base R;
48
49 250 however, instead of subsampling one-minute point samples, we subsampled 60 consecutive point
50
51 251 samples from a given focal female. We did this so the Gombe subsample more closely resembled
52
53
54 252 the sample of predominantly one-hour focal follows from LuiKotale. Lastly, we again restricted
55
56
57
58
59
60

1
2
3 253 our analyses to lactating females for which at least 20 hours of party scans were available for a
4
5 254 given infant age class (Table 2). Good observations included those one-minute point samples in
6
7
8 255 which the activity of the lactating female could be determined, as opposed to bad observations in
9
10 256 which the activity could not be determined due to poor visibility.

11
12 257

13
14
15 258 We used focal follow data to compare foraging and social budgets by analyzing the following
16
17 259 behaviors (following Lonsdorf et al. 2014):

18
19 260 1. Feeding – Ingestion of solid food.

20
21 261 2. Travel – Continuous movement from one point to another.

22
23 262 3. Social Interactions – Engaging in either of the following behaviors:

24
25
26 263 a. Social Groom – Parting of another individual’s hair with hands, fingers,
27
28 264 and/or lips and removal of debris or ectoparasites and/or receiving this
29
30 265 behavior from another individual.

31
32
33 266 b. Social Play – Non-aggressive interaction between two or more individuals that
34
35 267 include one or more of the following: tickling, wrestling, chasing, kicking,
36
37 268 rubbing, thrusting, biting, or pulling. May incorporate an object (e.g., tugging
39
40 269 of sticks back and forth).

41
42 270

43 44 271 **Statistical analyses**

45
46
47 272 We conducted all analyses in R version 4.0.2 (R Core Team 2020) and RStudio version 1.3.1
48
49 273 (RStudio Team 2020) using the glmmTMB version 1.0.2 (Brooks et al. 2018), DHARMA version
50
51 274 0.3.2 (Hartig 2020), car version 3.0-9 (Fox et al. 2012), and emmeans version 1.5.0 (Lenth 2018)
52
53
54 275 packages. To test our three predictions (described above), we fitted generalized linear mixed

1
2
3 276 models (GLMMs) to each response variable (response variables for each prediction described
4
5 277 below) using the glmmTMB function in the glmmTMB package with a beta-binomial error
6
7
8 278 structure. We initially fitted GLMMs using binomial error structures but found that all models
9
10 279 were overdispersed. Overdispersion occurs when variance is higher than predicted by the model
11
12 280 because the model lacks an adjustable dispersion parameter (e.g., as in binomial and poisson
13
14 281 models) (Bolker et al. 2009; Zuur et al. 2009). Beta-binomial models include an adjustable
15
16 282 dispersion parameter that allows the model to predict variance appropriately for binomial
17
18
19 283 proportion data (Harrison 2015). We reported results of nonparametric dispersion tests for all
20
21 284 models using the testDispersion function (case sensitive) in the DHARMA package. None of our
22
23
24 285 beta-binomial models exhibited overdispersion. We evaluated model assumptions by visually
25
26 286 assessing quantile-quantile plots and the distribution of residuals plotted against fitted values
27
28
29 287 using the simulateResiduals (case sensitive) function in the DHARMA package.

30
31 288
32
33 289 For all models, we first tested the interaction between species and infant age class. To determine
34
35 290 the significance ($\alpha = 0.05$) of interaction effects, we conducted Wald Chi-Squared tests using the
36
37
38 291 Anova (case sensitive) function in the car package (Kenward-Roger degrees of freedom
39
40 292 approximation, type III sum of squares). If the interaction between species and infant age class
41
42 293 was not significant, we removed it and refitted the model using species and infant age class as
43
44
45 294 independent fixed effect predictors and conducted Wald Chi-Squared tests, again using the
46
47 295 Anova function in the car package (Kenward-Roger degrees of freedom approximation, type II
48
49 296 sum of squares). If the interaction between species and infant age class was significant, we
50
51 297 conducted Tukey's pairwise post-hoc comparisons between species within each infant age class
52
53
54 298 using the emmeans function in the emmeans package. For all models, we included lactating

1
2
3 299 female identity as a random effect because the same lactating female could be represented in
4
5 300 multiple infant age classes.

6
7
8 301
9
10 302 To test our first prediction that lactating chimpanzees spend more time alone than lactating
11
12 303 bonobos, we ran one set of models called Time Alone (here and below, we refer to one set of
13
14 304 models as the interaction effect model followed by the refitted independent effects model if
15
16 305 necessary). We calculated our response variable by dividing the number of party scans that a
17
18 306 given lactating female was in a party alone with her immature offspring during each infant age
19
20 307 class by the total number of party scans collected on that lactating female during that infant age
21
22 308 class. We expected a significant interaction effect between species and infant age class or a
23
24 309 significant effect of species, with lactating chimpanzees spending more time alone than lactating
25
26 310 bonobos.

27
28
29
30
31 311
32
33 312 To test our second prediction that lactating females do not differ in feeding or travel time, we ran
34
35 313 two sets of models called Feeding and Travel. We calculated our response variables by dividing
36
37 314 the number of point samples that a given lactating female was engaged in feeding or travel,
38
39 315 respectively, during each infant age class by the total number of good observations collected on
40
41 316 that lactating female during that infant age class. We did not expect to find a significant
42
43 317 interaction effect between species and infant age class nor a significant effect of species.

44
45 318
46
47
48
49 319 To test our third prediction that lactating bonobos spend more time engaged in social
50
51 320 interactions, we ran two sets of models called Social Interactions and Adjusted Social
52
53 321 Interactions. We calculated our response variable for Social Interactions by dividing the number
54
55
56
57
58
59
60

1
2
3 322 of point samples that a given lactating female was engaged in social interactions during each
4
5 323 infant age class by the total number of good observations collected on that lactating female
6
7
8 324 during that infant age class. We calculated our response variable for Adjusted Social Interactions
9
10 325 by dividing the number of point samples that a given lactating female was engaged in social
11
12 326 interactions with individuals other than their immature offspring during each infant age class by
13
14 327 the total number of social interaction point samples collected on that lactating female during that
15
16
17 328 infant age class.
18

19 329
20

21 330 **RESULTS**

22
23
24 331 In support of our first prediction, we found that lactating chimpanzees spent more time alone
25
26 332 with their immature offspring than did lactating bonobos (Figure 1; Table 3). The interaction
27
28 333 between species and infant age class was not significant in the model for Time Alone ($X^2 =$
29
30 334 1.510 , $df = 2$, $p = 0.470$) (Table 4), but when we tested independent effects of species and infant
31
32 335 age class, species had a significant effect ($X^2 = 26.321$, $df = 1$, $p < 0.001$), while infant age class
33
34 336 did not have a significant effect ($X^2 = 0.414$, $df = 2$, $p = 0.813$). The nonparametric dispersion
35
36 337 tests were not significant for either Time Alone model (interaction effect model: deviance ratio =
37
38 338 0.957 , $p = 0.960$; independent effects model: deviance ratio = 1.002 , $p = 0.928$).
39

40 339
41
42
43

44 340 In support of our second prediction, lactating females of the two species did not differ in feeding
45
46 341 time (Figure 2) or travel time (Figure 3) (Table 3). The interaction between species and infant
47
48 342 age class was not significant in the model for Feeding ($X^2 = 4.359$, $df = 2$, $p = 0.113$) or Travel
49
50 343 ($X^2 = 0.850$, $df = 2$, $p = 0.654$) (Table 4). When we tested independent effects of species and
51
52 344 infant age class, species was not significant in either model (Feeding: $X^2 = 0.032$, $df = 1$, $p =$
53
54
55
56
57
58
59
60

1
2
3 345 0.857; Travel: $X^2 = 1.334$, $df = 1$, $p = 0.248$). However, infant age class had a significant effect
4
5 346 in both models (Feeding: $X^2 = 8.379$, $df = 2$, $p = 0.015$; Travel: $X^2 = 7.153$, $df = 2$, $p = 0.028$);
6
7 347 lactating females with older infants fed more (Figure 2) and traveled more (Figure 3) (Table 3).
8
9 348 The nonparametric dispersion tests were not significant for either Feeding model (interaction
10
11 349 effect model: deviance ratio = 1.066, $p = 0.496$; independent effects model: deviance ratio =
12
13 350 1.146, $p = 0.216$) or for either Travel model (interaction effect model: deviance ratio = 0.859, $p =$
14
15 351 0.200; independent effects model: deviance ratio = 0.895, $p = 0.328$).
16
17 352
18
19 353 Against our third prediction, lactating females of the two species did not differ in time engaged
20
21 354 in social interactions with any community member (Figure 4), and lactating chimpanzees spent
22
23 355 proportionately more of their social interaction time interacting with individuals other than their
24
25 356 immature offspring (Figure 5) (Table 3). The interaction between species and infant age class
26
27 357 was not significant in our model for Social Interactions ($X^2 = 0.870$, $df = 2$, $p = 0.647$) or for
28
29 358 Adjusted Social Interactions ($X^2 = 3.702$, $df = 2$, $p = 0.157$) (Table 4). When we tested
30
31 359 independent effects of species and infant age class in the model for Social Interactions, neither
32
33 360 species ($X^2 = 0.266$, $df = 1$, $p = 0.606$) nor infant age class ($X^2 = 2.745$, $df = 2$, $p = 0.253$) had
34
35 361 significant effects. When we tested independent effects of species and infant age class in the
36
37 362 model for Adjusted Social Interactions, species had a significant effect ($X^2 = 12.998$, $df = 1$, $p <$
38
39 363 0.001), but infant age class did not ($X^2 = 0.082$, $df = 2$, $p = 0.960$). The nonparametric dispersion
40
41 364 tests were not significant for either Social Interactions model (interaction effect model: deviance
42
43 365 ratio = 1.066, $p = 0.608$; independent effects model: deviance ratio = 1.043, $p = 0.704$) or for
44
45 366 either Adjusted Social Interactions model (interaction effect model: deviance ratio = 0.988, $p =$
46
47 367 1.000; independent effects model: deviance ratio = 0.977, $p = 0.984$).

368

369 **DISCUSSION**

370 Many studies across animal taxa indicate that fission-fusion dynamics allow individuals to
371 reduce feeding competition by adjusting the size and composition of the subgroups that they
372 range in (e.g., *Tursiops aduncus*: Heithaus and Dill 2002; *Ocaella heinsohni* and Sousa
373 *chinensis*: Parra et al. 2011; *Macropus giganteus*: Favreau et al. 2018; *Giraffa camelopardalis*:
374 Bond et al. 2019; *Neophron percnopterus majorensis*: van Overveld et al. 2020). Given that
375 feeding competition generally increases with increasing group size, females in fission-fusion
376 societies can offset the high energetic costs of lactation by reducing their levels of
377 gregariousness, thereby reducing feeding competition. We therefore hypothesized that lactating
378 chimpanzees at Gombe mitigate the intense feeding competition that they face by being less
379 gregarious than lactating bonobos, who are thought to facing less intense feeding competition. In
380 support of our first two predictions, lactating chimpanzees spent more time alone than lactating
381 bonobos, while feeding and travel time did not differ between the species. These result support
382 the hypothesis that lactating chimpanzees mitigate high feeding competition by being less
383 gregarious, given that in doing so they maintained foraging budgets comparable to their more
384 gregarious bonobo counterparts. Our results thus add evidence to the existing body of research
385 indicating that fission-fusion dynamics are a counterstrategy to feeding competition across taxa
386 (see above).

387

388 We also hypothesized that the social budgets of lactating chimpanzees are constrained as a result
389 of being less gregarious. However, we did not find support for this hypothesis: against our third
390 prediction, lactating females did not differ in total social interaction time, and lactating

1
2
3 391 chimpanzees spent proportionately more of their social interaction time interacting with
4
5 392 individuals other than their immature offspring. These results suggest that despite being less
6
7 393 gregarious, lactating chimpanzees spend as much time engaged in direct social interactions as do
8
9 394 lactating bonobos. It is therefore unclear how lactating bonobos benefit from higher
10
11 395 gregariousness if they do not engage in more social interactions when compared to lactating
12
13 396 chimpanzees. One possibility is that grouping provides lactating bonobos with opportunities to
14
15 397 enhance social relationships in ways that do not require direct interactions. In some animal taxa,
16
17 398 spatial association with conspecifics is related to fitness, and not necessarily direct social
18
19 399 interaction. For example, in the greater ani (*Crotophaga major*), females that consistently nested
20
21 400 together were considered to have stable social relationships, and this stability increased fitness
22
23 401 (Riehl and Strong 2018). Similarly, in feral horses (*Equus ferus caballus*), composite social
24
25 402 integration scores were positively related to fitness, and these scores were based on measures of
26
27 403 spatial affinity between mares (Cameron et al. 2009). Thus, there are numerous ways in which
28
29 404 gregarious individuals could gain social benefits without necessarily engaging in direct social
30
31 405 interactions. In this view, gregariousness could be favored at LuiKotale simply because being in
32
33 406 relatively close spatial proximity to other group members confers social benefits.
34
35
36
37
38
39
40
41

42 408 On the other hand, grouping may also provide lactating bonobos with opportunities for modes of
43
44 409 direct social interaction that we did not consider in our study. While our results indicate that
45
46 410 lactating chimpanzees invest more time in grooming and playing with the broader social milieu,
47
48 411 it may be that bonobos add to their social budget through other direct interactions. For example,
49
50 412 female bonobos engage in genito-genital rubbing, a behavior that is thought to contribute to bond
51
52 413 formation and maintenance (Furuichi 1989; Hohmann and Fruth 2000; Fruth and Hohmann
53
54
55
56
57
58
59
60

1
2
3 414 2006). Genito-genital rubbing requires little time investment as it more closely resembles a
4
5 415 behavioral event rather than a state. Female bonobos may thus have additional social currency at
6
7 416 their disposal that does not require substantial time investments, but it is difficult to make direct
8
9 417 comparisons with chimpanzees because chimpanzees do not habitually engage in genito-genital
10
11 418 rubbing (but see Anestis 2004; Zamma and Fujita 2004). Similarly, another mode of social
12
13 419 interaction not captured by our study is female-female coalitionary behavior. Female-female
14
15 420 coalitions against males are prevalent in bonobos (Surbeck and Hohmann 2013; Tokuyama and
16
17 421 Furuichi 2016; Nurmi et al. 2018) but not in chimpanzees (but see Newton-Fisher 2006), again
18
19 422 restricting direct comparisons between the species. It may be the case that benefits accrued
20
21 423 through modes of social interaction that we did not consider in this study are beneficial enough
22
23 424 to favor grouping by lactating bonobos.
24
25
26
27
28
29

30
31 426 More gregarious bonobos could also gain benefits associated with predator defense. Evidence for
32
33 427 variation in grouping patterns resulting from differences in predation risk is widespread across
34
35 428 non-primate taxa (e.g., *Suricata suricatta*: Clutton-Brock et al. 1999; *Junco hyemalis*: Lima et al.
36
37 429 1999; *Cervus elaphus*: Childress and Lung 2003; *Perdix perdix*: Watson et al. 2007); however,
38
39 430 such predator-prey systems are often characterized by relatively high rates of predation. In
40
41 431 generating our hypothesis, we assumed that grouping patterns are primarily driven by feeding
42
43 432 competition based on the limited empirical evidence for leopard predation on bonobos and
44
45 433 chimpanzees (see Introduction); indeed the underlying assumption of most fission-fusion
46
47 434 systems is that predation is sufficiently low enough to allow groups to fission (but see food-
48
49 435 safety tradeoff in *Tursiops aduncus*: Heithaus and Dill 2002). However, predation pressure is not
50
51 436 absent from LuiKotale. Leopards have not been observed at Gombe since roughly 1975 (see
52
53
54
55
56
57
58
59
60

1
2
3 437 Pierce 2009) and are presumed to be locally extinct; at LuiKotale, bonobo hard tissue was found
4
5 438 in leopard scat (D'Amour et al. 2006) and researchers recently observed a non-lethal
6
7 439 confrontation between bonobos and a leopard (unpublished data, Fruth and Hohmann),
8
9 440 suggesting that leopards are indeed a threat to bonobos. Thus, we cannot rule out that predation
10
11 441 risk at LuiKotale can have major impacts on bonobo sociality. This would be broadly in line with
12
13 442 the influential Predator Risk Allocation Hypothesis (Lima and Bednekoff 1999), which posits
14
15 443 that the trade-off between foraging and vigilance is less a function of immediate
16
17 444 presence/absence of predators and more of the temporal pattern of predation risk over time.
18
19 445
20
21
22
23 446 Irrespective of the costs and benefits of grouping, our finding that lactating chimpanzees can
24
25 447 maintain social budgets comparable to lactating bonobos despite reduced gregariousness
26
27 448 underscores the benefits associated with the flexibility in behavior that fission-fusion dynamics
28
29 449 provide. Bechstein's bats (*Myotis bechsteinii*) also illustrate this sort of flexibility: Kerth et al.
30
31 450 (2011) showed that individuals are able to maintain long-term social relationships despite high
32
33 451 fission-fusion dynamics. Similarly, we showed in a separate study that immature females from
34
35 452 LuiKotale and Gombe do not differ in time engaged in social play or social grooming, indicating
36
37 453 that the reduced gregariousness at Gombe does not constrain immature female social budgets
38
39 454 either (Lee et al. 2020). Results from our studies and the study by Kerth et al. (2011) suggest that
40
41 455 individuals in fission-fusion societies need not spend extensive time together in order to maintain
42
43 456 relationships with the broader social milieu. In those fission-fusion species for which social
44
45 457 relationships are likely critical components of fitness, selection may have favored social skills
46
47 458 that enable bond partners to maintain relationships even with limited association time. Future
48
49 459 research could evaluate this further by identifying the mechanisms by which individuals develop
50
51
52
53
54
55
56
57
58
59
60

1
2
3 460 and maintain such relationships in species that appear to exhibit even less frequent encounters
4
5 461 with some associates, such as African forest elephants (*Loxodonta cyclotis*) (Fishlock and Lee
6
7 462 2013) or sperm whales (*Physeter macrocephalus*) (Whitehead et al. 1991). More specifically,
8
9
10 463 such research could focus on the role of different latencies between fusions within and between
11
12 464 species to determine whether it is the absolute amount of time that individuals associate and/or
13
14 465 the temporal patterning of fusions that influences bond formation and maintenance.

FIGURE LEGENDS

Figure 1

Mean \pm *SE* percentage of time that lactating females spent ranging in parties with only their immature offspring. Note: This figure and all following figures represent raw data; asterisks indicate where the independent fixed effect of species was statistically significant.

Figure 2

Mean \pm *SE* percentage of time that lactating females spent feeding.

Figure 3

Mean \pm *SE* percentage of time that lactating females spent traveling.

Figure 4

Mean \pm *SE* percentage of time that lactating females spent engaged in social interactions with any community member.

Figure 5

Mean \pm *SE* percentage of social interactions in which lactating females spent engaged in social interactions with individuals other than their immature offspring.

Table 2

Focal follow sample size

Infant age class	Bonobo	Bonobo	Chimpanzee	Chimpanzee
	female	male	female	male
0 < 1.5	4 125	4 177	4 120	6 172
1.5 < 3	3 119	1 23	2 140	1 23
3 < 4.5	3 99	2 63	3 97	2 62

Number of lactating females | total focal follow observation time

Table 3

GLMM parameter estimates for independent effects models

Model	Term	Estimate	SE	z	<i>p</i>
Time alone	Intercept	-3.804	0.509	-7.481	-
	Chimpanzee	2.470	0.481	5.130	< 0.001
	Infant age class 1.5 < 3	-0.267	0.419	-0.637	0.524
	Infant age class 3 < 4.5	-0.140	0.405	-0.345	0.730
Feeding	Intercept	-0.507	0.109	-4.662	-
	Chimpanzee	-0.023	0.126	-0.180	0.857
	Infant age class 1.5 < 3	0.354	0.151	2.344	0.019
	Infant age class 3 < 4.5	0.319	0.132	2.411	0.016
Travel	Intercept	-1.606	0.069	-23.338	-
	Chimpanzee	-0.093	0.080	-1.155	0.248
	Infant age class 1.5 < 3	0.251	0.094	2.657	0.008
	Infant age class 3 < 4.5	0.105	0.085	1.242	0.214
Social Interactions	Intercept	-1.755	0.115	-15.224	-
	Chimpanzee	0.067	0.130	0.516	0.606
	Infant age class 1.5 < 3	-0.157	0.163	-0.960	0.337
	Infant age class 3 < 4.5	-0.249	0.162	-1.534	0.125
Adjusted Social Interactions	Intercept	-3.101	0.210	-14.802	-
	Chimpanzee	0.782	0.217	3.605	< 0.001
	Infant age class 1.5 < 3	-0.082	0.298	-0.276	0.782
	Infant age class 3 < 4.5	-0.031	0.229	-0.135	0.892

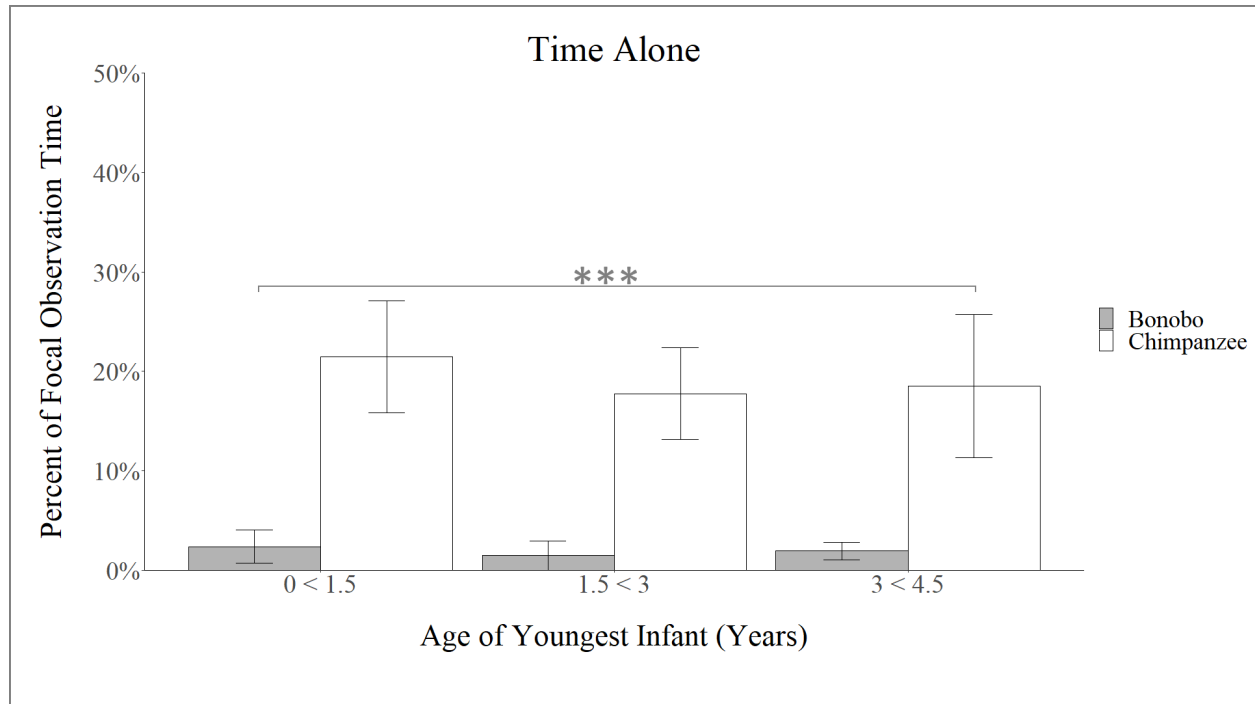

Table 4

GLMM parameter estimates for interaction effect models

Model	Term	Estimate	SE	<i>z</i>	<i>p</i>
	Intercept	-3.900	0.719	-5.425	-
Time Alone	Chimpanzee * Age 1.5 < 3	0.680	1.302	0.523	0.601
	Chimpanzee * Age 3 < 4.5	-0.805	1.03	-0.779	0.436
	Intercept	-0.484	0.116	-4.013	-
Feeding	Chimpanzee * Age 1.5 < 3	0.531	0.284	1.871	0.061
	Chimpanzee * Age 3 < 4.5	-0.054	0.249	-0.215	0.829
	Intercept	-1.593	0.078	-20.415	-
Travel	Chimpanzee * Age 1.5 < 3	0.204	0.259	0.788	0.431
	Chimpanzee * Age 3 < 4.5	-0.069	0.164	-0.422	0.673
	Intercept	-1.749	0.126	-13.840	-
Social Interactions	Chimpanzee * Age 1.5 < 3	-0.126	0.324	-0.390	0.696
	Chimpanzee * Age 3 < 4.5	0.206	0.292	0.705	0.481
	Intercept	-2.910	0.211	-13.799	-
Adjusted Social Interactions	Chimpanzee * Age 1.5 < 3	0.506	0.495	1.023	0.306
	Chimpanzee * Age 3 < 4.5	0.878	0.470	1.869	0.062
