14

15

16   **After the end-Cretaceous extinction, placental mammals quickly diversified[1], occupied key**

17   **ecological niches[2,3], and increased in size[4,5], but the latter was not true of other therians[6].**

18   **The uniquely extended gestation of placental young[7] may have factored in their success and**

19   **size increase[8], but reproduction style in early placentals remains unknown. Here, using**

20   **palaeohistology and geochemistry, we present the earliest record of a placental life history,**

21   **in a 62-million year old pantodont, the clade including the first mammals to achieve truly**

22   **large body sizes. We extend the application of dental trace element mapping[9,10] by sixty**

23   **million years, identifying chemical markers of birth and weaning, and calibrate these to a**

24   **daily record of growth in the dentition. A long gestation (~7 months), rapid dental**

25   **development, and short suckling interval (~30–75 days) show *Pantolambda bathmodon* was**

26   **highly precocial, unlike non-placental mammals and known Mesozoic precursors. These**

27   **results demonstrate *P. bathmodon* reproduced like a placental, and lived at a fast pace for**

28   **its body size. Assuming *P. bathmodon* reflects close placental relatives, our findings suggest**

29   **the ability to produce well-developed precocial young was established early in placental**

30   **evolution, and that larger neonate sizes were a possible mechanism for rapid size increase**

31   **in early placentals.**

32

33

34   Placentals are the most diverse group of mammals, comprising >6,000 extant species[11] and the

35   largest animals ever. Their success may relate to their derived life history[8,12], with maternal

36   investment shifted prenatally through extended gestation[7,13]. This adaptation allows placentals

37   the unique capability among mammals to produce highly precocial young: typically single

38   offspring born at larger masses with well-developed dentition, fur, and open eyes[13,14]. Extended

39 gestation may have released placentals from developmental constraints associated with

40 prolonged lactation in other mammals[8,15,16], enabling experimentation with new locomotor

41 modes and habitats[17,18]. However, when extended gestation evolved in mammals remains

42 unclear: Mesozoic eutherians (mammals more closely related to placentals than marsupials) did

43 not grow like living placentals[19–21] and it has been hypothesized that ancestral placentals gave

44 birth to altricial young[21]. Nonetheless, immediately after the end-Cretaceous extinction, early

45 Palaeocene placentals emerged from a 100-Ma lineage of small-bodied ancestors and quickly

46 achieved much greater masses as they diversified into a variety of niches[4]. Thus, the early

47 Palaeocene was likely an important interval in the eutherian transition to placental-like growth

48 strategies, but the life histories of these mammals remain unknown.

49   Among early placental clades, the Palaeocene–Eocene Pantodonta are a key group,

50 because they were among the first large mammalian herbivores, becoming the largest mammals

51 ever up to that point in time[22]. The early Palaeocene (~62 ma) *Pantolambda bathmodon* (~42 kg)

52 is represented by multiple skeletons representing most of its ontogeny, including a small juvenile

53 with deciduous dentition and unfused epiphyses (New Mexico Museum of Natural History and

54 Science [NMMNH] P-27844; ~17 kg at death). As one of the largest mammals in its

55 ecosystem[23], its life history might provide insight into the relationship between life history and

56 body size in Palaeocene eutherians.

57   Life histories of extinct animals can be reconstructed using incremental growth features

58 of mineralized tissues like bones and teeth[24–26]. Bones preserve evidence of stress and annual

59 cycles[27,28], and they accurately reflect growth rate throughout life[29,30], including changes

60 associated with maturity[31]. In teeth, daily incremental lines in the dentine and enamel allow for

61 precise chronologies and faithful recording of life history events such as birth and nutritional

62 stress like that experienced during weaning[32,33], whereas cementum preserves annual growth

63 cycles[24,34]. Chemical signals of birth and early-life diet are recorded in the developing teeth by

64 the abundances of certain trace elements, like zinc (Zn), which is enriched at birth[35,36], and

65 barium (Ba), which varies according to bioavailability in the diet[26]. When integrated with daily

66 growth increments, trace elements maps can reveal birth and the timing of weaning, a technique

67 applied to primates up to 2.6 million years old[9,10,26], but with unrealised potential in other fossil

68 mammals.

69   Here we combine palaeohistological and geochemical evidence to reconstruct the life

70 history of *P. bathmodon* on a daily scale and evaluate the physiology of a key group in the rise of

71 mammals following the end-Cretaceous mass extinction. These data provide unprecedented

72 insight into the life history of a fossil mammal, revealing that characteristic placental

73 reproductive strategies were established early in their evolution.

74

75 **Dental development, birth, and weaning**

76   Incremental growth features are well preserved in the teeth, especially the enamel, and

77 are clearly visible in histological thin sections (Fig. 1b–g; Extended Data Fig. 1). Daily

78 laminations in the dentine and enamel[37] (Fig. 1b, c, e) track the successive growth of the tooth

79 crown (Extended Data Table 1). High-resolution trace element mapping of several teeth

80 (Extended Data Table 1; Figs. S1–7) reveals patterns in Zn and Ba that correspond to these

81 incremental growth patterns and provide evidence of birth and weaning in *P. bathmodon* (Fig. 2),

82 extending the viable window for dietary trace element mapping by roughly 60 million years

83 compared to previous studies[10]. The most complete record of early life comes from a second

84   lower molar of an adult individual (NMMNH P-19541), where both the neonatal event and the

85   weaning transition are preserved (Fig. 2).

86   Birth is recorded in the enamel by a prominent neonatal line (Fig. 1g; 2b), a discontinuity

87   in the enamel prisms reflecting developmental disruptions in response to the physiological stress

88   of birth[38]. The neonatal line is Zn-enriched (Fig. 2b; Extended Data Fig. 2), as observed in

89   modern teeth, where this results from changing levels of Zn in serum over the birth interval and

90   the ingestion of Zn-rich colostrum[35,36]. Importantly, the neonatal line is Zn-enriched in multiple

91   cusps of the tooth, and no other accentuated lines in the enamel of this or other teeth are Zn-

92   enriched (Fig. 2b, see Supplement). This suggests that analysis of Zn may be useful as an

93   independent criterion for distinguishing neonatal lines from other accentuated lines in fossil

94   mammals[36].

95   Concentrations of Ba in the enamel are elevated postnatally, but decrease sharply after a

96   short period (Fig. 2c). This pattern is present in both the protoconid and paraconid of the second

97   lower molar, as well as in the first lower molar of the same individual (Fig. 2d), indicating that it

98   represents a consistent biogenic signal. Temporary postnatal Ba enrichment in *P. bathmodon* is

99   identical to that reported in modern and fossil primates[9,10,26], where it reflects the increased

100   bioavailability of Ba in breastmilk[26]. The decrease in Ba presumably marks the onset of weaning

101   and indicates a minimum suckling period of about 31–56 days in *P. bathmodon*. Further

102   independent evidence for a short suckling period also comes from mesowear and microwear in

103   the dentition of a young juvenile (NMMNH P-27844; Extended Data Fig. 3), where growth

104   increments in the dentine of the deciduous teeth are exceptionally well preserved (Fig. 1c;

105   Extended Data Fig. 1). Like in the enamel, a birth signature appears to be recorded in the dentine

106   by a neonatal line, and in this individual the postnatal dentine is Zn-enriched (Extended Data Fig.

107   4). Dentine continues to infill the pulp cavity throughout life, providing a record of growth both

108   before and after eruption of the tooth and allowing precise estimation of age at death[24].

109   Approximately 75 daily growth increments separate the neonatal line and the pulp cavity in each

110   tooth of this juvenile skeleton, indicating an age at death of ~2.5 months for this individual.

111   Despite its young age, the presence of dental meso- and microwear[39] (Extended Data Fig. 3) in

112   this individual shows that solid foods (not only milk) were being ingested, providing an upper

113   constraint of 75 days on the onset of weaning.

114   Aligning daily growth records in the teeth based on the neonatal lines enables the

115   reconstruction of a dental chronology (Fig. 1l). Crown formation times in the teeth are rapid,

116   ranging from 68 days to 183 days (~2–6 months; Extended Data Table 1). All of the deciduous

117   teeth were complete and began erupting before birth, and the first and second adult molars had

118   begun mineralizing. The adult molar crowns were completed within four months after birth and

119   would have begun erupting in the first year. Based on eruption sequences in other pantodonts[40–

120   42], where the third molar erupts last, it is therefore likely that all of the adult teeth of *P.*

121   *bathmodon* erupted within the first year (see Supplement).

122   In the permanent teeth of mammals, age at death can be estimated from annual bands in

123   the cementum that anchors the tooth to the jaw[24,34]. Cementum annulations are clearly present in

124   the acellular cementum of most teeth in our sample (Fig. 1d). Most individuals have between two

125   and four annual pairs (Extended Data Table 1), but three individuals with highly worn dentitions

126   compared to other Palaeocene pantodonts have five, seven and possibly as many as eleven pairs,

127   respectively (Extended Data Figure 5; see Supplement).

128

129   **Skeletal growth**

130   The bone microstructure of the juvenile skeleton (NMMNH P-27844) exhibits densely

131   vascularized fibrolamellar bone, indicating relatively rapid growth (Fig. 1i–k). No annual growth

132   marks are present, consistent with its dental age of ~2.5 months, but a band of more organized,

133   slowly-growing parallel-fibered bone occurs towards the outer surface of the radius and tibia

134   (Fig. 1i; Extended Data Fig. 6), at an estimated mass of 9 kg (see Supplement). External to this

135   band, the bone shows reduced vascularity and relatively slower growth, based on a higher

136   proportion of parallel-fibered matrix (Fig. 1j,k), although laminations in this tissue are not as

137   well developed as in the lamellar bone of the adult individual. This transition likely corresponds

138   to changes in growth rate associated with weaning, as in living ungulates a similar transition

139   occurs in some individuals over this interval[43] (see Supplement). The position of this transition

140   partway through the cortex provides evidence for weaning in this individual prior to death at 2.5

141   months of age, supporting the 1–2 month suckling period suggested by dental trace elements and

142   tooth wear.

143   In a skeletally mature adult (NMMNH P-22012), seven annual growth marks are

144   discernible in the exterior cortical bone, matching the number of cementum annulations in its

145   teeth and demonstrating that it was seven years old when it died. The exterior cortex is formed of

146   highly organized lamellar bone, indicating slow growth (Fig. 1h). The earliest annual growth

147   mark is within the slowly-growing exterior cortex (Extended Data Fig. 7), indicating that growth

148   rate decreased significantly before the end of the first year of life. This likely corresponds to the

149   achievement of sexual maturity[31], suggesting that *P. bathmodon* likely reached sexual maturity

150   and approached maximum body size in its first year.

151

152   **Life history in *Pantolambda bathmodon***

153   Correcting for the onset of tooth mineralization partway through fetal development (see

154   Supplement), the prenatal growth record in the deciduous teeth indicates a gestation period of

155   roughly 207 days or 29.5 weeks. This is an order of magnitude longer than in marsupials or

156   monotremes, but falls close to extant placentals of similar body size (Fig. 3b). Within placentals,

157   gestation length is dichotomous between species that give birth to single or multiple young in

158   each litter[44] (Fig. 3c). The long gestation period in *P. bathmodon* suggests it was likely (posterior

159   probability = 0.96) to have given birth to singleton offspring (see Supplement).

160   Multiple independent lines of evidence from two individuals indicate the onset of

161   weaning between 1–2 months after birth in *P. bathmodon*. Postnatal enrichment in enamel Ba for

162   1–2 months after birth in an adult individual (Fig. 2c, d) is consistent with the development of

163   abrasive microwear and mesowear on the dentition of the 2.5-month old juvenile (Extended Data

164   Fig. 3) and with the transition recorded in its limb bones (Extended Data Fig. 6), identical to

165   weaning transitions recently described on the basis of fluorescent labelling[43]. Together, these

166   lines of evidence constrain weaning in *P. bathmodon* to between 31 and 75 days after birth, with

167   the weight of evidence supporting cessation of suckling by 2 months after birth. The age (31–75

168   days) and mass (9 kg) at weaning in *P. bathmodon* were shorter and smaller than expected for a

169   placental of its adult body mass, but its gestation period (207 days) was slightly longer (Fig. 3a,

170   b). This indicates greater prenatal than postnatal investment in the young, characteristic of

171   placental mammals[7], but also suggests a distinct life history for these early Palaeocene

172   placentals, consistent with other unusual aspects of their biology[45].

173   Most individuals within our sample died between 2–5 years of age (Fig. 1l), suggesting

174   high mortality rates in young animals. The oldest specimen in our sample (estimated to be ~11

175   years old) lived only half the expected lifespan for a mammal of its body mass (20 years; Fig.

176   3d). This high mortality rate, in conjunction with its short suckling period and rapid onset of

177   sexual maturity (Fig. 3a, e), suggest a fast pace of life in *P. bathmodon*, despite its relatively

178   large size (42 kg).

179   Combined with its rapid dental and skeletal development, these life history parameters

180   indicate a highly precocial lifestyle in *P. bathmodon*, comparable to the most precocial extant

181   mammals (e.g., deer, giraffes, sheep), which give birth to young with hair and open eyes[13,14].

182   After a long gestation—the hallmark of the typical placental reproductive mode—a mother *P.*

183   *bathmodon* likely gave birth to a single, haired offspring with open eyes and well-developed

184   dentition, which nursed for 1–2 months. At ~62 Ma, this constitutes the earliest example of a

185   placentalian-grade physiology in the fossil record.

186

187   **Growth in early placentals**

188   The growth pattern and rate of *P. bathmodon* differs from both those of Mesozoic

189   mammaliaforms[19,34] and other Cenozoic mammals[46,47]. The mammaliaform *Morganucodon* grew

190   at a much slower rate and for longer period, evidence of a protracted life history more like that of

191   reptiles than mammals[19,34]. Late Cretaceous multituberculates and some eutherians had faster

192   growth rates than *Morganucodon*, but these were still not as rapid as extant mammals[19]. In

193   contrast, *P. bathmodon* exhibits fast growth rates and a rapid developmental schedule, more

194   similar to living precocial placentals. Nonetheless, *P. bathmodon* lived and died faster than

195   expected for a mammal of its body size, outpacing extant mammals and even other extinct

196   mammals from later in the Cenozoic[46,47]. The closest living analogues for *Pantolambda*,

197   independent of mass (Extended Data Fig. 8a), are small antelope, like the neotragines *Madoqua*

198   (Dik-dik) and *Raphicerus* (Steenbok). However, when adult body mass is considered,

199   *Pantolambda* is unique among terrestrial mammals (Extended Data Fig. 8b). This life history

200   strategy would have enabled *P. bathmodon* to proliferate at a rapid rate for an animal of its size,

201   which may have been advantageous in the recovering ecosystems of the Palaeocene. Perhaps, as

202   was the case with locomotion[45] and brain size[48], placental life history strategies became limited

203   to their modern range later, as ecosystems saturated.

204   In contrast to its distinctly rapid pace of life, the gestation period of *P. bathmodon* is

205   remarkably similar to living placentals of its body mass (Fig. 3b; Extended Data Fig. 8),

206   suggesting a more constrained relationship between size and gestation. Indeed, neonate weight

207   and adult body mass are more tightly correlated than other life history parameters in extant

208   placentals (Extended Data Fig. 9), suggesting that neonate weight drives and/or is constrained by

209   adult body mass. As longer gestation enables the larger neonate sizes required for larger adults

210   (Extended Data Fig. 9c), extended gestation periods like that in *P. bathmodon* may have

211   contributed to the rapid increase in body mass in early Palaeocene placentals. The option of

212   extended gestation may have reduced developmental constraints on body size and allowed

213   placentals to expand into vacant niches after the extinction of the non-avian dinosaurs, reaching

214   larger sizes than any Mesozoic mammal[22], and culminating in the largest animals ever[49].

215   The excellent preservation of daily incremental structures and dietary trace element

216   signatures in a ~62 million year old fossil unlock a new perspective for studying the life history

217   of extinct mammals. Our results suggest that biogenic trace element signals can be retained much

218   longer than previously realized, providing new tools for inferring birth and early-life diet in

219   ancient fossil mammals. Rather than being a limitation for studying reproduction, the

220   abundantly-preserved isolated teeth of Mesozoic mammals may enable combined

221   palaeohistological and geochemical approaches to directly address the evolution of reproduction

in mammals, including its role in their survival at the end-Cretaceous extinction and their radiation thereafter. Indeed, the highly precocial life history of *P. bathmodon* shows that the physiology of at least some close placental relatives had diverged from other mammals by at least the Palaeocene, early in their evolutionary history[21], and suggests that the capacity to increase body size played a role in their ascent from humble Mesozoic beginnings to the dominant role they play in global ecosystems today.

Fig. 1. Palaeohistology of *Pantolambda bathmodon*. (a) Skeletal reconstruction of adult with sampled elements in blue; boxes show representative locations of palaeohistological images, silhouette shows relative size of juvenile NMMNH P-27844. (b–g) dental features used for reconstruction of life history (all coronal sections): (b) enamel cross-striations (arrows) in second lower molar of NMMNH P-19541; (c) lines of von Ebner in deciduous ultimate upper premolar of NMMNH P-27844, white dots mark five lines and arrows show orientation of lines; (d) cementum annulations (one light + one dark band) in first lower premolar of NMMNH P-69919; (e) daily laminations (arrows) in lower incisor of NMMNH P-69918; (f) neonatal line in dentine of deciduous ultimate upper premolar of NMMNH P-27844; and (g) neonatal line (arrow) in enamel of second lower molar of NMMNH P-19541. (h–k), osteohistological features used for reconstruction of life history (all transverse midshaft diaphysis sections): (h) lines of arrested growth (arrows) in outer cortex of rib of NMMNH P-22012; (i) annulus (orange arrow) at weaning transition in radius of NMMNH P-27844; (j–k) weaning transition (arrows and yellow line) in outer cortex of tibia of NMMNH P-27844 under plane polarized light (j) and cross-polarized light with a lambda filter (k). Images (b–g, i) under cross-polarized light, (h) under cross-polarized light with a lambda filter. (l) life history chronology of *P. bathmodon* showing crown formation times for deciduous (blue) and adult (green) teeth, life history events, and mortality. Daggers indicate ages at death, youngest and oldest specimens highlighted in blue.
Abbreviations: CCCB, compact coarse cancellous bone; **DEJ**, dentinoenamel junction; **WB**, woven-fibered bone; **glg**, growth layer group; **LB**, lamellar bone; **NNL**, neonatal line; **PFB**,

376   parallel-fibered bone. Scale bars: 10 cm (a), 25 μm (b), 50 μm (e), 100 μm (c, d), 200 μm (f–h),

377   500 μm (i–k).

378

379   **Fig. 2.** Trace element distributions in the enamel of the first and second lower molars (NMMNH

380   P-19541; also see Figs. S1–3). (a) Thin section under cross-polarized light shows clear daily

381   laminations and the neonatal line (dotted line) in the enamel of the paraconid of the second lower

382   molar. (b) Trace element map of Zn shows enrichment at the neonatal line. (c) Barium is

383   enriched in early postnatal enamel (also see Supplementary Fig. S8), but decreases gradually

384   between 31–56 days after birth (dashed lines). (d) The transition between high and low Ba is

385   clearer in the paraconid of the first lower molar of the same individual, where older enamel

386   including the neonatal line has been worn away. (e,f) overview images showing position of

387   images within first (f) and second (e) lower molars. Scale bars: 500 μm (a–d), 1 mm (e, f).

388

389   **Fig. 3.** Comparison of the reconstructed life history of *Pantolambda bathmodon* (black

390   diamonds) to extant mammals using the PanTheria Dataset[50]. Suckling period, showing the range

391   (31–75 days) estimated for *P. bathmodon* based on dental trace elements, bone histology, and

392   dental wear (a); gestation period (b), violin plot of gestation period sorted by litter size (c),

393   maximum lifespan, showing data from PanTHERIA (grey, solid line) and from the wild-only

394   lifespan dataset of Newham et al.[34] (orange, dashed regression line) (d), and age at sexual

395   maturity (e) for living mammals (green: placentals; blue: marsupials; purple: monotremes)

396   plotted against adult body mass ($\log_{10}$ g). Trendlines show generalized linear model regressions

397   for placentals, marsupials, and monotremes, with 95% confidence intervals for the regression

398   indicated by shaded envelopes. Horizontal lines show untransformed values. Silhouettes for each

399   panel show living taxa similar in the reconstructed parameter to the estimate for *P. bathmodon*.

400   Silhouette of *Pantolambda bathmodon* created by SLS. Silhouettes of *Acinonyx*, *Antilocapra*,

404   https://creativecommons.org/publicdomain/zero/1.0/).

405

406

407   **Methods:**

408   We prepared thin sections (see Supplementary Information) of the teeth and bones of 12

409   specimens of *Pantolambda bathmodon*, including two partial skeletons and totalling 45 elements

410   (23 bones and 22 teeth), collected from the Torrejonian NALMA of the Nacimiento Formation in

411   the San Juan Basin of New Mexico, USA[51]. The specimens were selected to represent as much of

412   the skeleton and as many tooth positions as possible and to capture varying degrees of dental

413   wear, presumably attributable to individuals of different ages. The minimum number of

414   individuals based on skeletal overlap *a priori* was three, but age variation indicates a minimum

415   of seven individuals in our palaeohistological sample.

416   Incremental marks in the cementum, dentine, and enamel were counted from thin-

417   sections to assess the timing and pace of tooth development. Cementum annulations, lines of von

418   Ebner in the dentine, and cross-striations in the enamel were each clearly visible under cross-

419   polarized light. Pairs of one light and one dark band in the acellular extrinsic fiber cementum

420   near the cervix of the tooth were counted as growth layer groups representing annual growth

421   cycles[24,52,53]. Lines of von Ebner in the dentine, clearly distinct from more broadly spaced

422   Andresen lines[24,54], were counted from high-magnification photomontages as daily increments of

423   growth. Likewise, cross-striations in the enamel were interpreted as daily increments of

424   growth[54,55]. In every specimen, enamel cross-striations were aligned into clearly visible growth

425   laminations, which have a daily periodicity[37,56]. The neonatal line in the enamel was identified as

426   a prominent, Zn-enriched[35] accentuated line formed by discontinuities in the enamel prisms. In

427   the dentine of the deciduous teeth, the earliest accentuated stress line was identified as the

428   neonatal line[24], which was supported by consistent changes in Zn concentration across the

429   neonatal boundary[35,57] (Extended Data Fig. 4). The neonatal line was used to demarcate pre- and

430   post-natal developmental periods, and to align sequences from different tooth positions within

431   and between individuals. Daily growth increments in the enamel were traced from high-

432   resolution photomontages to create temporal maps of daily dental development for each tooth.

433   Enamel secretion, crown extension, and crown formation rates were estimated using the methods

434   of Dirks et al.[47]

435   Dietary trace element concentrations were assessed using laser-ablation inductively

436   coupled-plasma mass spectroscopy (LA-ICP-MS) at the University of Edinburgh and the

437   University of St. Andrews Isotope Geochemistry (STAiG) lab. After pilot runs using an ATLEX-

438   I-LR Analyte Excite 193 nm ArF excimer coupled to an Attom ICPMS, Nu Instrument at the

439   University of Edinburgh, to assess the suitability of the material for analysis, a broad array of

440   trace element concentrations (^{11}B, ^{23}Na, ^{25}Mg, ^{27}Al, ^{31}P, ^{43}Ca, ^{46}Ca, ^{55}Mn, ^{59}Co, ^{60}Ni, ^{63}Cu, ^{66}Zn,

441   ^{88}Sr, ^{89}Y, ^{138}Ba, ^{208}Pb, and ^{238}U) in the enamel and dentine of six teeth were mapped using LA-

442   ICP-MS on an Agilent 8900-QQQ at the STAiG lab. Entire enamel sequences of three teeth (the

443   paraconid of a lower first molar [NMMNH P-19541], the protoconid of a lower second molar

444   [NMMNH P-19541], and the labial enamel of an incisor [NMMNH P-69918]) were scanned at

445 high resolution (20 μm spot size, 10 μm s^{-1} scanning speed, ICP cycle time 0.2889 s), with an

446 effective pixel size of 60 μm^2 (Figs. S1–4). Small regions of interest in the deciduous teeth

447 (NMMNH P-27844) were also scanned at high resolution (38 μm spot size, 38 μm s^{-1} scanning

448 speed; Figs. S5–7). LA-ICP-MS data were processed and rasterized in Iolite v4.5.5.4[58].

449 Concentrations were normalized to and drift-corrected by a NIST 612 glass standard after gas

450 blank subtraction, and standardized to ~40% Ca. Elemental maps and transects were registered to

451 temporal maps of dental development to evaluate daily changes in diet.

452   Dental microwear was evaluated using scanning electron microscopy (SEM) using a Carl

453 Zeiss SIGMA DH VP field emission SEM at the University of Edinburgh operated at 15 kV for

454 secondary electron imaging of the fine-scale features of the occlusal surface of the first upper

455 molar of NMMNH P-27844.

456   Reconstructed life history parameters for *P. bathmodon* were plotted alongside data from

457 the PanTHERIA dataset[50] for comparison. Because the PanTHERIA dataset includes mostly

458 captive individuals, which are likely to have greater maximum lifespans than wild individuals,

459 the estimated maximum lifespan of *P. bathmodon* was also compared to a recent wild-only

460 dataset of mammal maximum lifespan[34]. Relative importance of life history parameters for

461 predicting body size was evaluated using multiple regression, and litter size was predicted using

462 linear discriminant analysis based on gestation period. Principal components analysis was used

463 to identify the closest living analogues of *P. bathmodon*.

583   **Extended Data Fig. 6.** Weaning transition recorded in the postcranial bones of NMMNH P-

584   27844. (a) Transverse section of right humerus diaphysis under cross-polarized light, showing

585   arrangement of tissues and large medullary cavity and location of close-up image. (b) Close-up

586   of cortex of right humerus under cross-polarized light, showing increase in proportion of

587   parallel-fibered bone (brighter tissues) later in growth (arrow), indicative of a decrease in growth

588   rate. (c) Transverse section of right tibia diaphysis under plane polarized light, showing location

589   of close-up image. (d) Close-up of cortex of right tibia under cross-polarized light with a lambda

590   filter, showing transition (arrow) from highly-vascularized fibrolamellar bone with a high

591   proportion of woven-fibered matrix (upper right) to more slowly-growing parallel-fibered bone

592   with reduced vascularity (lower left). (e) Transverse section of right radius diaphysis under

593   cross-polarized light, showing location of close-up image. (f) Close-up image of cortex of right

594   radius under cross-polarized light with a lambda filter, showing annulus of parallel-fibered bone

595   (arrow) separating region of highly-vascularized fibrolamellar bone (lower right) from region of

596   less-vascularized fibrolamellar bone with a higher proportion of parallel-fibered bone (upper

597   left). Scale bars: 1 mm (a, c, e), 500 µm (b, d, f).

598

599 **Extended Data Fig. 7.** Transition to slower growth likely reflecting sexual maturity. (a) Coronal

600 section of posterior dentary of NMMNH P-22012 under cross-polarized light with a lambda

601 filter, showing locations of close-up images. Dark regions have been diagenetically altered by

602 the deposition of opaque minerals. (b, c) Close-up of transition (dashed line) between faster-

603 growing fibrolamellar bone (flb) and slower-growing lamellar bone (lb), indicative of sexual

604 maturity, under cross-polarized light (b) and cross-polarized light with a lambda filter (c).

605 Arrows indicate first line of arrested growth, deposited after the transition to slower growth.

606 Scale bars: 1 mm (a), 200 μm (b, c).

607

608 **Extended Data Fig. 8.** Life history of *P. bathmodon* compared to living mammals. (a, b)

609 principal components analyses using the PanTHERIA dataset (placentals, green; marsupials,

610 blue; monotremes, purple) incorporating suckling interval, gestation period, maximum lifespan,

611 and age at sexual maturity, with adult body mass excluded (a) or included (b) as a variable; close

612 living analogues to *P. bathmodon* indicated by silhouettes. (c–f) regressions of life history

613 variables in placental mammals with 95% confidence intervals (thin black lines) centred on the

614 generalized linear model regression trendline for suckling interval (c), gestation period (d),

615 maximum lifespan (e), and age at sexual maturity (f), showing that *P. bathmodon* is within the

616 95% confidence interval of placentals in all parameters. Silhouette of *Pantolambda bathmodon*

617 created by SLS. Silhouettes of *Orycteropus* and *Priodontes* adapted from Phylopic images (CC0

618 1.0 https://creativecommons.org/publicdomain/zero/1.0/), silhouette of *Leptonychotes* is original

619 artwork by GFF, silhouette of *Phoca* was generated from a photograph taken by GFF, and all

620 others were generated from public domain images (CC0 1.0

621 https://creativecommons.org/publicdomain/zero/1.0/).

622

Extended Data Fig. 9. Relationship between neonate mass and adult body mass in extant

mammals. (a) Generalized linear model regression of neonate body mass against adult body mass

for all species in the PanTheria dataset, showing clear separation of placental mammals (green,

p-value $< 2.2 \times 10^{-16}$) from non-placental mammals (p-value: 4.07×10^{-6}); 95% confidence interval

for regression slope shown as shaded envelope. (b) Neonate body mass plotted against adult

body mass for placental species, showing tight correlations of neonate mass and adult mass (p

values both $< 2.2 \times 10^{-16}$) ; 95% confidence interval for generalized linear model regression slope

shown as shaded envelope. (c) Gestation period plotted against neonate body mass; 95%

confidence interval for generalized linear regression slope shown as shaded envelope. (d)

Relative importance of multiple regression of adult body mass against neonate weight, gestation

period, maximum lifespan, time to sexual maturity, and suckling period, showing relative

contribution of factors to adult body mass; confidence intervals derived from 1000 replicates of

bootstrapping.

Extended Data Table 1. Quantitative dental histological data for *Pantolambda bathmodon*.

Note: *estimate, see Supplement for further details. For teeth with a neonatal line, † prenatal, ‡

postnatal. §, counted as a pair of light and dark bands; - inapplicable or not available;
